This is also made evident by an examination of the legal measures against tuberculosis, adopted within the last year or two. One law contains the regulation that a very considerable subvention shall be paid by the State to such sanatoria, tuberculosis hospitals, etc., as admit patients of the poorer classes for a fixed low maximum payment; to those sanatoria in which the daily payment is only 80 cents, the law authorizes the Government to pay three-fourths of the amount, so that only 20 cents a day need be paid by the patient himself. Another law provides that persons in public service suffering from tuberculosis of an infective character and continually coming in close contact with the population (as, for example, school teachers), be at once pensioned, the pension being fixed at two-thirds of the patient's regular wages. Of course we have also a whole series of regulations for the notification of cases and deaths, free disinfection, and so forth. But the supervision of the persons affected with tuberculous diseases cannot compare with the admirable work done by the Department of Health of the city of New York as described in a recent number of the MEDICAL RECORD.

The school vacation has now begun, and at the same time another and, as I believe, very effective move has been made in our struggle with tuberculosis. As in other countries, public charity has provided vacation homes, open-air campments, etc., for the poor school children. But as a rule, I think, these very meritorious institutions suffer under certain shortcomings, in as far as they cannot become a home to their little protégés in the full meaning of the word, because of the great number they have got to harbor. Therefore I should not have touched upon this subject if a happy solution of a very important question had not been found here, viz., how to procure an outing for the poor school children of great cities. For years a very great number of the farmers of the whole country have spontaneously offered to take free of cost into their families children from the public schools of the metropolis, each farmer taking one or two children. The number of pale, weak children that enjoy in this way a vacation of four to six weeks amounts to about 20,000. The more businesslike part of the transaction, the filing of applications, etc., is carried out gratuitously by the teachers in the schools. The State gives free tickets on railways and steamboats to the place of destination. But the farmers get no other remuneration but the gratitude of their little guests and the joy of witnessing the great improvement in the looks of the children after their sojourn in the country has come to an end.

In order to prevent this letter from treating only topics of medicosociological interest, I shall briefly mention a recently published investigation of more than usual interest. Dr. Hans Jansen of the Finsen Light Institute of Copenhagen has inquired into the manner of action of the Finsen light treatment. Finsen himself has expressed as his opinion that in order to be therapeutically active the light ought to be able to kill the microbes, to provoke inflammation, and to penetrate as far as possible into the tissues. In other words, he ascribed a great part of the efficacy of the treatment to the bactericidal powers of the light used. Now Jansen's researches, partly in confirmation of the results of other modern investigators, tend to show that the Finsen treatment has no appreciable action except on the uppermost layers of the skin, as it loses its activity 0.5 or at all events 1 mm. below the surface. The alterations of the tissues of the treated region consist in a destruction of the cellular elements, especially also of those of the blood vessels, while the connective tissue is but little or not at all affected. This is the reason why as a rule no microscopic necrosis is observed and why the affected tissues heal up so beautifully. In the tissue under treatment may further be observed dilatation and thrombosis of the vessels, accompanied by serous exudation and diapedesis. One of the most interesting statements is that the tuberculosis bacilli are killed only in the uppermost 0.2 mm. of the influenced tissue, the rest of them being thrown off, together with the necrotic tissue in which they are situated. In other words, the treatment can only be said to derive its efficacy to a very little degree from the bactericidal powers of the light. It is, therefore, probable that the very scarcity of the bacilli in lupus vulgaris contributes considerably toward the good results of the treatment in this disease. Of the different rays contained in the light only the ultraviolet ones are

active. The visible chemical rays, the blue-violet ones, have scarcely any, the red, yellow, and green ones no importance whatever, for the usual Finsen treatment.

During the summer months our hospitals have the pleasure of seeing as guests quite a number of American doctors. They never take leave of us without expressing their regret that they did not know before of the excellent opportunity for studying to be found here. And, to be sure, in no other place are they more welcome or will they meet with more kindness at the hands of their colleagues than here.

HYDROCHLORIC ACID IN CHOLERA.

To the Editor of the Medical Record:

Sir:—Having noticed in a recent issue of the Medical Record Dr. Heiser's letter concerning the failure of quinine in cholera, and knowing that so far other methods of treatment do not yield any better results, I am prompted to suggest the trial of a treatment which seems to me to be very rational.

I have shown in previous articles detailing the results of my researches on the bacteria of the stomach (Medical Record, November 19, 1904; *American Medicine*, February 24, 1906) that in cases of normal gastric juice and in hyperchlorhydria, after a light meal as well as when fasting, there are, as a rule, only three varieties of microorganisms to be met with in the stomach, viz., yeast, a small bacillus which I have named *B. chlorhydrici*, and sarcinæ, usually of the lutea type. By keeping such gastric juice for weeks in a nonsterilized test-tube, stoppered with a nonsterilized plug of cotton, no other microbes appear. Normal gastric juice, then, as well as that of hyperchlorhydria, is germicidal to almost all bacteria. Even the colon bacillus, which is not so much affected by acids as are the cholera and the typhoid bacilli, cannot thrive in such juice. In hypochlorhydria, however, any microbe may be found. Now, we can assume from the above with reasonable certainty that when the cholera bacillus is swallowed by one whose gastric juice contains 2 per 1,000 of hydrochloric acid, it will be destroyed in a few minutes. But if one suffers from chronic hypochlorhydria or from acute gastritis anacida, or when the stomach is so overloaded that the gastric juice is too dilute and weak, he can easily become a victim of cholera or typhoid fever.

I would therefore suggest the following treatment in cholera: Wash out the stomach well, through the stomach tube, with warm water, previously boiled, containing 2 per 1,000 of hydrochloric acid, and at the end of the lavage introduce into the stomach, through the tube, from 300 to 500 c.c. of the same solution, and leave it there. A soft rubber tube can be introduced with safety, provided the operator has experience. Repeat the above treatment every four hours. The intestines should also be well irrigated, but with a weaker solution (1 per 1,000) of hydrochloric acid.

I regret I cannot try this treatment myself, because I have no cholera patients, but I hope some one will give it a fair trial; it seems to be more rational than any that has been in vogue. In addition, I would advise those who are in a cholera or typhoid district, especially those who come in frequent contact with the patients, to have their gastric contents examined, and if there is any deficiency in the gastric juice, to supply it freely by taking liberal doses of hydrochloric acid, and also of pepsin if it is deficient, as the two act well together. E. Palier, M.D.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 9, 1906.

Adams-Stokes Disease, with Report of Three Cases.—Walter S. Steiner says this disease is an affection which presents clinically the following features: (1) A slow pulse, usually permanent, but sometimes paroxysmal, falling to 40, 20, or even 6 per minute; (2) cerebral attacks which consist in vertigo of transient character, syncope, pseudoapoplectiform attacks, or epileptiform seizures; and (3) visible auricular impulses in the veins of the neck, the beats varying greatly, a 2:1 or 3:1 rhythm being the most common. The disease is most commonly seen in persons past middle life. Males are more frequently affected. Syphilis and myocardial changes appear to be contributing factors.

Treatment of Tuberculous Laryngitis in Sanatoria.—George L. Richards states that such statistics as he has been able to find would seem to show that positive laryngeal lesions are present in at least 15 to 20 per cent. of all cases of tuberculosis, and some statistics give the proportion as very much higher. The ideal treatment of laryngeal tuberculosis is one in which the local measures can be judiciously and helpfully carried out during the continuance of climatic treatment. The question of the proper care and treatment of these cases should be more seriously considered, especially so since these early and incipient cases are especially suitable for sanatorium treatment, where silence and a proper regime can be carried out.

Accident Litigation.—Frank C. Richardson writes of the widespread and constantly increasing demands for exorbitant sums as compensation for real or fancied injuries resulting from alleged negligence of corporations or individuals, a form of "graft" not only threatening the financial welfare of some of our larger business interests, but especially pernicious in that by reason of its temptations to conscious or unconscious perversion or exaggeration of fact, it is damaging to the moral integrity of the masses who are its most frequent perpetrators.

New York Medical Journal, August 4, 1906.

A Modified Operation for Movable Kidney.—J. Chalmers DaCosta has long been dissatisfied with the suture operation for movable kidney, and has practised the following operation in twenty cases, to his entire satisfaction. The exposure of the kidney is identical with the method of Senn, and the kidney is brought out of the wound as advocated by Edebohls. The fatty capsule is cut away and the fatty capsule is either scraped or rubbed with gauze, or decapsulated. The ends of two pieces of iodoform gauze are sewed together with slender plain catgut for use for the upper and the lower pole of the kidney. Therefore, instead of passing one long piece of iodoform gauze beneath a renal pole, and being obliged subsequently to pull a long end around under the kidney, when the gauze is to be removed, a sutured piece of gauze is placed under the renal pole and, as the sutures are composed of fine plain catgut, they quickly absorb and, in a few days, the gauze is easily delivered, and, the suture line being directly under the kidney, there is only a short end to pull around on each side.

The Surgical Significance of Jaundice.—Samuel Lloyd says that the changes in the blood and the condition of the kidneys must be most carefully considered in the surgical treatment of jaundice. A change in the coagulability of the blood is one of the most dreaded conditions to meet, and its exact cause one does not know. Lloyd refers to this as a pseudohaemophilia. In these cases it may require 13 minutes or longer for coagulation to occur. Such hemorrhages begin as a rule from one to four days after operation. In all cases of prolonged jaundice there is a marked and generally increasing anemia. Surgical operations performed when the hemoglobin percentage is below 30 are exceedingly serious; if it has fallen to 20 a fatal result is almost certain. Changes in the kidney are important, more in determining the anesthetic to be employed and in influencing the prognosis. In cirrhosis surgical relief may be possible. He has done the Talma-Morrison-Drummond operation seven times, and he believes it is worth while to attempt this operation in those cases where the ascites is great and the patient is losing ground.

Rational Treatment of Visceral Ptosis.—J. Madison Taylor offers briefly a few facts and opinions, with a résumé of his own experience, in the treatment of visceral ptosis. This subject is an illustrative instance to emphasize the principle that we should reach back in our efforts to the original defect, the correction of which conserves constitutional depravity from its earliest divergence, and we should amplify the inherent organic resources to the utmost. We should not fail to start at the beginning, the *fons et origo mali*, and not waste time in correcting only obvious derangements. It is always desirable to avoid operation if equal results can be secured by rehabilitating the inherent forces. His opinion is positive that displacements and ptosis of the viscera can, in nearly all instances, be restored. The etiological factors underlying the visceral ptosis, particularly dilatation and motor insufficiency, depend in large part on lessened vasoconstrictor tone. Among the most influential factors in aggravating the ptosis are dyspepsias, intestinal fermentations, and putrefactions.

Journal of the American Medical Association, August 11, 1906.

Surgery of the Biliary Tract.—J. B. Deaver is in favor of removing gallstones whenever present, provided there are no contraindications, and also considers cholecystotomy the safest treatment of any frank attack

of acute cholecystitis that does not subside under judicious medical measures in thirty-six or forty-eight hours. Operation is almost imperative if the attack is not the first and it is believed from the history that gallstones are present. In mild recurrent cases operative interference is indicated, and also in the later stages of gall-bladder disease. In hydrops, cholecystectomy is required, as the closing of the cystic duct renders the gall-bladder useless, and there is constant danger of reinfection or even of rupture. Cholecystectomy is also indicated in gangrene and perforation, but not in empyema, except when of long standing and with the walls very extensively diseased. When gallstones exist the condition is more serious, and the patient is fortunate if they can be removed before they wander from the gall-bladder. The advantages of operation in the latent stages are pointed out. Deaver protests against any indiscriminate resort to cholecystectomy in operating for impacted stone in the common duct unless the gall-bladder is very much diseased. He believes that its retention and drainage constitute a very valuable part of the after-treatment. When the infection has traveled beyond the gall-bladder and involved the hepatic ducts, or even if the cystic duct is very much infiltrated, he would drain the common duct as well. Patients who during typhoid fever give evidence of biliary involvement should, if possible, undergo cholecystostomy on recovery if their symptoms persist, thus not only avoiding future serious disease, but also more effectually preventing their dissemination of typhoid infection from the intestinal tract.

Capillarity in Intestinal Sutures.—F. G. Connell has tested the capillarity of intestinal sutures in order to ascertain whether or not through-and-through sutures of all the bowel coats would be likely to produce infection of the serosa. He experimented with various suture materials, silk, catgut, celluloid, etc., under differing conditions of moisture, tension, etc., both in colored intestinal fluid contents and with plain colored fluids outside the body, and also in living animals in which a loop of intestine was isolated by ligatures and colored solutions injected into the isolated section. The time allowed for the capillarity to manifest itself was two hours, as that would be sufficient for the formation of a plastic exudate that would of itself be protective. The conclusion reached from the experiments, which were generally negative as regards any serious penetration of the coats or infection of the serosa, is that the danger from capillarity has been greatly overestimated, and that it should no longer be considered an objection to the through-and-through stitch. By employing a square or right-angled, instead of a round or whip stitch, the extent of the suture material on the serosa may be reduced to a minimum, and that little can be separated from the general peritoneal cavity by serous apposition.

Birdshot Injuries of the Eye.—W. P. Marple reports two cases of birdshot injuries of the eye, both cases of double perforation. In one of them enucleation was practised. In the second case the shot was located by the *x*-rays. He discusses the diagnosis and prognosis of these injuries and refers to a number of cases of interest in the literature. Except when there is a lacerated wound in the ciliary region, or when the eyeball is disorganized by numerous shot entering it at close range, he considers the prospect of saving the eyeball is generally fair, but as to the preservation of sight, that depends on the parts involved. If the course of the shot is through the peripheral structures, and especially when there is a double perforation, the visual disturbance is principally due to hemorrhage, and it may take months for absorption to be complete. Penetration of the eyeball is not an essential condition for serious results; they may occur without it. In his second case, the vision was 20/20 at the end of five months and absorption, he thinks, was still continuing. When a shot remains in the eye it may do mischief if it rests near the ciliary body, but he does not consider that its mere presence will be necessarily irritating. If the shot is in an accessible position, attempt should be made to get it out, as when it lies near the ciliary body, where it will probably set up irritation. Otherwise it may become encapsulated. If the eye is badly lacerated immediate enucleation is advisable. If the perforation is single the principal thing is to prevent infection. Accurate *x*-ray pictures should be taken to locate the shot, and if a double perforation is shown, the eye can probably be saved, if the ciliary body is not injured and if infection does not occur. Probing is strongly condemned. With hemorrhage in the vitreous the iodides may be useful in assisting absorption.

The Lancet, July 28, 1906.

Appendicitis and Gangrene of the Vermiform Appendix Considered as Separate Diseases.—The object of this paper by John D. Malcolm is to show that in a considerable number of cases of mischief connected with the vermiform appendix the initial lesion is a formation of a gangrenous patch in the wall of that part of the intestine, a condition that is frequently associated with an appendicitis beginning in the mucous membrane but which may arise independently. He concludes that gangrenous patches forming in the wall of the appendix may bring about three well defined conditions and which are independent of inflammation beginning in the mucous membrane. First there may be an escape into the peritoneal cavity of microorganisms which excite serous, a seropurulent or a purulent exudation unlimited by adhesions. Second, the adjacent peritoneum may become adherent over a gangrenous patch and the latter separates and is discharged through the appendix, recovery taking place. Third, a gangrenous patch may thus become sealed off, but when it separates the adhesions also give way and a localized abscess forms or a rupture into the peritoneal cavity takes place. If an exact diagnosis between the signs and symptoms of inflammation of the appendix beginning in its mucous membrane and those of the gangrenous formation which occasionally occurs in its walls could be made, the treatment would be much simplified, but the differential diagnosis may be very difficult.

The Passage of Spirochæta Duttoni from Mother to Fetus.—Anton Breinl, as a result of experimental work on the organism of African relapsing fever, comes to the following conclusions: (1) *Spirochæta duttoni* passes through the placenta from the circulation of the mother to that of the fetus. (2) The majority of the fetuses carried by an infected mother are themselves infected. (3) The parasites are found in the placenta in approximately the same numbers as in the maternal heart blood, but, on the contrary, occur in very scanty numbers in the fetal circulation. (4) The spirochetes in the fetal circulation show no morphological changes. (4) Infected pregnant rats show no tendency towards abortion, but few of their young, in comparison with those from healthy mothers, reach maturity. (6) The young born of infected mothers possess no marked inborn immunity against infection either by means of direct inoculation or through the bites of ticks.

The Electrical Resistance of the Blood and Urine as a Test of the Functional Efficiency of the Kidney.—Dawson F. D. Turner finds that the specific resistance of a normal urine amounts to about 45 ohms and that the resistance is a measure of the salts present in the urine; the greater the concentration the less the resistance and *vice versa*. In disease the resistance was found to be increased chiefly in acute croupous pneumonia, in diabetes mellitus, acute and chronic Bright's disease, and in pernicious anemia. In the latter disease, the resistance was usually one-half that of normal blood and the deduction was that the blood in this disease contains an abnormal amount of salts due either to destructive metabolism or to renal inefficiency, or both. The resistance of the urine was found to be abnormally high; hence there is the striking fact that while the urine contains too few salts the blood contains an abnormal amount, a clear case of renal insufficiency.

The Possible Importance of Earthworms as a Factor in the Spread of Disease.—Charles F. Fraser considers the existence in the alimentary canal of lumbricus or allolobophora of a vast number of parasitic organisms, some being rendered peculiarly virulent by their passage through the worm. The tatanus bacillus especially being rendered so and thus [illegible] possible explanation of the frequency of infection among grazing horses. In the posterior part of the gut nematode is found which has a great similarity to trichina spiralis. Infection of a pig may occur from contamination of the herbage with worm-casts, or the pig may eat the lumbricales themselves.

British Medical Journal, July 28, 1906.

Errors of Refraction Among Children Attending Elementary Schools in London.—A. Hugh Thompson states that the average age of the children examined under 10 was 9; and at this age 23.4 per cent. of those with defective sight, or 2.34 per cent. of the children on the register, were myopic. Four years later, at an average age of 13, the proportion was 31.3 per cent. of those with defective sight, or 3.13 of those on the register, an increase of 1 in 125. There was an ap-

parent increase of hypermetropia in children over 12 and a decrease of mixed astigmatism. There was a continuous decrease of hypermetropic astigmatism as the children grew older. He concludes his paper by stating that of the total number of children who need glasses, about one-quarter need simple convex spheres. Excluding cases of myopic astigmatism, nearly half of the children who need glasses at all, need cylindrical glasses, or a cylindrical combination. Myopic children, with or without astigmatism, are about 3 per cent. of the whole number in all elementary schools. In very young children myopia exists to a greater extent than has hitherto been generally realized.

The Varieties of Ringworm and Their Treatment.—James H. Sequeira says that in his country the commonest form by far is *Microsporon audouinii;* next in order comes the large-spored *Tricophytons,* and last, the favus fungus, *Achorion schonleinii.* The first of these is exceedingly difficult to treat because the fungus extends into the hair follicles and the remedies applied cannot penetrate sufficiently. The fungus is easily reached by parasiticides when the disease affects parts which are not hairy. With the exception of those cases in which the beard is affected, the ectothrix ringworms are less resistant to treatment than the diseases due to the endothrix and microsporon fungi. The treatment of ringworm of the non-hairy parts is rarely a matter of great difficulty and the compounds of mercury are most useful. Thoroughly wash the parts with soft soap and warm water, and then rub in the white precipitate ointment. Ointment of oleate of mercury is another good preparation. Oleate of copper has its advocates. Sulphur and sulphurous acid are also valuable. In the treatment of ringworm of the scalp and beard regions a very satisfactory epilating agent is to be found in the *x*-ray. In most cases the hair starts growing again in six to eight weeks after treatment. It should be remembered that the *x*-rays have no lethal effect on the parasite; their sole virtue is that they bring the hairs out with the fungus. The rest of the scalp should be protected against the falling hairs.

Thyroid Gland in Obesity.—W. J. Hoyten says that the best results are obtained in females between the ages of 35 and 45 years. He uses tablets containing 2½ grains and one tablet is taken with each meal. After seven days the dose is increased to five grains with each meal. Alcohol is prohibited in any form. Of 78 women treated, 69 were between 25 and 45, their average weekly loss was 2½ to 4 lbs., and the result was permanent cure; 9 were between 15 and 19, and there was no permanent result in any of them. Of 25 men 9 were between 30 and 47; they lost on an average 2 to 3½ lbs., and the cure was permanent; 11 men between 30 and 47 lost 1 to 1½ lb. on an average, but the result was not permanent; on 5, between 14 and 17, there was no effect at all.

Berliner klinische Wochenschrift, July 23, 1906.

The Agglutination of Typhoid Bacilli by Bile.—Venema says that the discovery that a certain group of individuals exists who are chronic typhoid bacilli carriers has led to the search for some means of rendering such people free from the organisms. Persons of this description are not unlikely to be sources of infection to others and it is, therefore, of great importance to do away with this source of danger. So far all efforts in this direction have been in vain, however, and the various intestinal disinfectants, astringents, and purgatives employed have not accomplished the desired results. Since it has been recognized that the gall bladder serves as the breeding place for the typhoid bacilli under these conditions, attempts have been made to devise some plan of treatment by immunization. It is therefore necessary to investigate the action of bile on typhoid bacilli and the author has carried out a series of experiments with this end in view. The agglutinating and bactericidal power of the bile of individuals dying of diesases other than typhoid was tested, as well as that of normal experiment animals. The result showed that there was no agglutinating nor bactericidal power in such specimens of bile, and Forster and Kayser have already discovered that the bile of immunized animals also has no bactericidal power. It therefore appears that there is little probability of success in attempting to destroy the typhoid bacilli in the gall bladder by any immunizing process.

The Application of Wright's Opsonin Theory.—Weinstein reviews the underlying principles of Wright's opsonin theory, which he says has not yet received the recognition it deserves in Germany. He describes the technique as practiced by Wright and gives the case histories and opsonic curves of eleven cases of acne and furunculosis which were treated with vaccine prepared from the patient's own staphylococci in accordance with Wright's teaching. In all of these very satisfactory results were obtained and the author expresses himself as favorably impressed with the method. In most of the cases the negative phase of Wright was observed immediately after the first inoculation and the positive phase, attended by an improvement in the clinical picture, usually occurred after two or three inoculations. In most cases the first injections were followed by a reaction of which malaise and weakness were the chief symptoms. There was no elevation of temperature. In some instances the patients complained of moderate tenderness at the site of injection. The best results were obtained by using small doses at first and continuing these until a cumulative positive phase was produced, that is, the opsonic index remained persistently high. Only after this has occurred should the dose be increased.

Münchener medizinische Wochenschrift, July 24, 1906.

The Value of Ahlfeld's Method of Hand Disinfection.—Herff states that he considers it a serious injustice that so little attention has heretofore been paid to the hot-water-alcohol method of hand disinfection devised by Ahlfeld, and that even the leading text-books either omit all reference to it or speak of it slightingly. Herff has tested it on 5,000 parturient women treated in the Maternity Hospital of Basle during the period from November, 1901 to May, 1906, and the results obtained he considers are so excellent as to form an exceedingly strong argument in favor of the method. The total mortality during this period was .7 per cent; there were no deaths form puerperal infection, and elevations of temperature above 38° C. were observed in only 8.2 per cent. of the cases. The two most important advantages afforded by the hot-water-alcohol sterilization are its simplicity, since only two scrubbings of about five minutes each are required, and the fact that the alcohol tans and dries the skin so that the number of germs cast off in the course of an operation either by the operator's hands or the skin of the patient is greatly reduced. The author attaches considerable importance to the protection of the skin about the incision with dry towels rather than by any impervious material, as he considers that if the latter is used there is much greater likelihood of wound contamination.

The Treatment of Spinal Palsies of Children.—Vulpius discusses the various procedures available for the treatment of spinal palsies that have reached a permanent stage. He is somewhat averse to the use of apparatus except in selected cases owing to the many disadvantages that attend its use. In cases of total paralysis with flail joints arthrodesis is very useful and gives particularly satisfactory results in treating flail joint at the shoulder. In dealing with partial palsies, tendon transplantation, although of comparatively recent development, has become one of the most therapeutic procedures at our command, and Vulpius believes it will be found more and more universally applicable. He himself has had a very large number of permanently satisfactory cases and he urges that the method be more frequently applied.

Allergy.—Pirquet proposes the use of this term to express the altered faculty of reaction exhibited by an organism that has been inoculated with some specific substance. Recently the phenomena of oversensitiveness following immunization have become widely recognized and have been made the subject of much study, but it is a misnomer to speak of immunity and oversensitiveness as existing in the same individual. Pirquet, therefore, would restrict the term immunity to those processes in which the introduction of the foreign substance into the organism does not produce any clinical reaction; that is, complete nonsensitiveness exists. The condition of increased sensitiveness shown by those who have been inoculated with vaccine, the virus of syphilis, or tuberculin, for example, comprises "allergy." the individuals themselves are to be spoken of as being "allergic," and substances which, when introduced into the body, produce an alteration in its powers of reaction are "allergens."

Deutsche medizinische Wochenschrift, July 26, 1906.

Garrulitas Vulvæ.—Schulein says that two theories are held in regard to the nature of this affection. The adherents of the one believe that the gas expelled audibly from the vulva is formed by gas-forming bacilli in the vagina, while others are of the opinion that atmospheric air is aspirated into the vagina and

is then expelled, either immediately or after the lapse of some time. The author, who describes in detail two cases of this affection, holds the latter view and considers that relaxation of the vagina and vulva after childbirth and relaxation of the abdominal parietes are the most important predisposing factors. The treatment consists in astringent irrigations and sitz baths, together with the attempt to improve the muscular tone of the entire body. If these measures are not successful colpoperineorrhaphy will usually afford relief. The affection is one which is much commoner than is ordinarily believed, as the patients of the lower classes do not consider it important enough to consult a physician about, while those of the higher walks of life are likely to feel diffident about seeking medical aid on this account.

Observations on the Living Spirochæta Pallida.—Beer says that he has been able to keep living spirochetes under observation in microscopical preparations during a period of thirty-three days. The material studied was obtained from primary lesions, mucous patches, and buboes. Beer found that the conventional hanging drop preparation was less satisfactory than the use of an ordinary slide and cover glass, evaporation being prevented by ringing the cover glass with vaseline and wax. In such preparations it can be seen that the spirochetes exhibit two forms of motility, namely, rotation about their long axis and lateral movements of the entire body. When the organism comes in contact with a cell the rotary motion is particularly marked and the organism appears to be attempting to penetrate the cell membrane corkscrew fashion. In fresh preparations most of the spirochetes promptly attach themselves to the cellular structures in this way so that the periphery of blood corpuscles, epithelial cells, etc., is a good place in which to look for the organisms. The author was not able to observe division of a living spirochete, but he witnessed what appeared to be the beginning of a longitudinal fission so that a Y-shaped form resulted. No development changes were noted in the spirochetes during the period they were under observation.

French and Italian Journals.

Ovarian Insufficiency.—Paul Carnot reviews Frankel's conclusions in regard to this subject. Ablation of the ovaries performed sometime after fecundation of the ovum arrests pregnancy. Ablation of the ovary besides this effect brings about atrophy of the uterus. The ovary governs the nutrition of this organ. It is the corpus luteum which exercises this function, for the destruction of these bodies by the thermocautery is followed by the same effect as is the extirpation of the entire gland. The destruction of this body in the course of a laparotomy prevents menstruation. The corpus luteum has a structure like that of the other glands producing an internal secretion. It gives to the uterus a cyclic nutritive impulse and prepares the mucosa to receive the fertilized ovum. If the ovum is fertilized the corpus luteum persists and increases the nutritive function of the uterus, the mucosa of which envelops the ovum and allows it to develop. If the fertilization does not occur the corpus luteum produces hyperemia of the uterus, which ends in menstruation. The corpus luteum must be considered a small ovarian gland which is regenerated periodically and which presides over the nutrition of the uterus from puberty until the menopause. The writer then cites various instances of ovarian insufficiency in which the administration of the extract of this gland has been followed by gratifying results.—*Le Progrès Médical,* June 16, 1906.

Liver Abscess of Appendicular Origin.— Véron relates his observations of a patient who was successfully operated upon for appendicitis. There was neither suppuration nor adhesions. The appendix was long and swollen and was resected. The condition of the patient was grave in the days following the operation. The wound suppurated and was opened up. It was then tamponned with iodoform gauze. It was not until the fifteenth day that the existence of a liver abscess was recognized. A second operation was performed and thick pus was evacuated. The pus was full of bloody streaks, but was without the chocolate color of the liver abscess of dysenteric origin. The temperature fell, the general condition improved, and the operative wound granulated. Six weeks after operation, however, a new liver infection developed. A purulent retention was suspected. The wound, which had not yet healed over, was probed with the finger, and it was discovered that the first cavity communicated with a second pocket. Drainage and dressing were renewed. Four times purulent intrahepatic collections were evacuated. Finally the patient entirely recovered.—*La Presse Médicale,* June 16, 1906.

Cystic Swelling of the Ovaries in a Patient With Hydatidiform Mole.—Goullioud calls attention to the coexistence of hydatidiform mole and a special cystic degeneration of the ovaries. He has recently observed a woman twenty-five years old, mother of two children, who toward the fourth month of the third pregnancy had a bloody discharge. On either side of the fundus of the gravid uterus were two symmetrical tumors. These were oblong, the size of a fetal head, slightly movable, and distinct from the uterus. The patient expelled an hydatiform mole. This was followed by a phlebitis. The tumors progressively decreased in size until they regained the normal dimensions. Two years later the patient again became pregnant. She was confined at the fourth month. The fetus was normal and the placenta showed no trace of degeneration. Six months later the patient was in a perfectly normal condition. The writer declares that the condition was rather cystic tumefaction than cystic degeneration of the ovaries. In this patient these organs resumed their normal functions. In such a case there is no indication to practise ovariotomy.—*Lyon Médical,* June 17, 1906.

Bacterium Coli and the Potability of Water.—Elio Tirelli says that it has been generally believed that the presence of bacterium coli in a specimen of water was a sufficient indication of its unfitness for drinking purposes. Other authors have given no value to this test, on account of the ubiquity of this germ. The author has examined water from eight different sources in the city of Parma in order to ascertain how frequent this germ is in waters, and what is its relation and that of the bacteria similar to the colon bacillus to the potability of water. He made careful chemical and bacteriological examinations of all the specimens. He concludes that the bacterium coli is not by any means ubiquitous, since he found it present in 25 per cent. of the specimens, and the similar bacteria with it in 18 per cent. The presence of these bacteria should be considered a sufficient indication of the impurity of any water. When the bacilli similar to the colon bacillus alone are found they do not indicate an impurity that renders the water unfit for drinking.—*Giornale Medico del Regio Esercito,* May, 1906.

A Mixture of Air and Chloroform as an Anesthetic.—Gréhant in his experiments with animals used a mixture of chloroform vapor and air, in the proportion of ten grams of chloroform to one hundred liters of air. He chose two dogs, one weak and sick, the other strong and vigorous. The first was anesthetized with the 10 per cent. mixture. The animal showed no excitement, but its temperature was lowered several degrees. One hundred c.c. of blood contained only twenty-one milligrams of chloroform. The second dog was subjected to the action of the same strength of chloroform. It showed strong excitement. In order to calm the animal it was necessary to employ a stronger mixture. Fifteen grams of chloroform to one hundred liters of air produced complete anesthesia. The rectal temperature did not vary. One hundred c.c. of blood contained fifty-two milligrams of chloroform. Gréhant concludes from his experiments that the surgeon must employ doses of chloroform for anesthesia varying according to the strength of the patient.—*Le Bulletin Médical,* May 30, 1906.

Cystic Sarcoma of the Mesocolon.—This case was in Jaboulay's service. The patient was a man thirty-six years old, a miner. The personal history was negative. Three months before his entrance to the hospital he suffered from malaise and sometimes from pains in the lower part of the abdomen, which obliged him to stop work for a while. There seemed to be no other symptom. He had not lost strength, and he showed no signs of intestinal or urinary disturbance. His abdomen appeared to be increasing in size. Palpation detected a tumor. Within two months this growth had attained a considerable size. On his entrance to the hospital the patient was not emaciated, nor did he suffer pain. Operation was performed, and the tumor was removed. Recovery was complicated with phlebitis, with pulmonary embolism. It is now about six weeks since the operation and the patient is pronounced well.—*Lyon Médical,* June 3, 1906.

A Prolonged Case of Typhoid Fever with Many Relapses.—Paul Claisse describes this case. The duration of the fever was two hundred days. The first attack was followed by five relapses, each of which lasted from ten to fifteen days. The benign character of relapses in typhoid fever has often been emphasized. This cannot be regarded as an absolute rule. In the present case the life of the patient was in danger from intestinal hemorrhages in one of the relapses. Aside from this, however, the illness was uncomplicated and the nervous symptoms were slight. Serodiagnosis proved without doubt that this was an instance of typhoid fever. With regard to paratyphoid bacilli of various origins, the results of the tests were negative. They were constantly positive in regard to the typhoid bacillus.—*La Presse Médicale,* June 6, 1906.

Book Reviews.

THE MEDICAL DISEASES OF INFANCY AND CHILDHOOD, with Points on the Anatomy, Physiology, and Hygiene Peculiar to the Developing Period. By ALFRED CLEVELAND COTTON, A.M., M.D., Professor of Pediatrics, Rush Medical College, University of Chicago; Attending Physician for the Diseases of Children, Presbyterian Hospital; Consultant to the Central Free Dispensary, etc., etc. Formerly Physician-in-Charge of the Chicago Isolation Hospital and of the Infectious Disease Wards of the County Hospital. Member of the Thirteenth International Medical Congress, Moscow. Honorary Member of the Société d' Hygiène, Paris, etc. Philadelphia and London: J. P. Lippincott Company, 1906.

IN this excellent contribution to the literature on pediatrics, the author has wisely laid special emphasis on the subject of prophylaxis, which under the heading of "Anatomy, Physiology, and Hygiene of the Developing Period," comprising the first part of the work, he has indicated as the foundation upon which must rest all rational and scientific treatment of disorders of infancy and early childhood. This first part of the work, comprising chapters on "Normal Growth and Development," "Physiology and Hygiene of the Newborn," "Natural, Supplemental, and Artificial Feeding," with a brief discussion on "Food Essentials," etc., is an excellent introduction to the consideration of pathological conditions forming the second and, of course, principal part of the work. In Part One the author is perhaps somewhat specious in his treatment of some of the features under the heading of "Hygiene of the Nursery." This speciousness, however, is compensated by very practical though albeit somewhat dogmatic discussion of other important subjects. The author's contention is certainly reasonable, that successful treatment of infantile diseases demands, so to speak, readjustment of the ordinary association of pathological and clinical manifestations as applied to adult life.

Part Two consists of sixteen chapters covering pretty thoroughly all of the diseases of infancy and early childhood, very satisfactorily grouped, and an appendix comprising remarks on "Sickroom Hygiene" and a formulary of the more commonly needed antiseptic solutions, correctives, astringents, etc. The chapters on "Diseases of the Heart," "Diseases of the Respiratory Tract," and "Diseases of the Nervous System" are especially good, clear, and concise. The book is well indexed, the illustrations are particularly instructive, and on the whole the work is very readable and is especially adapted to the requirements of the general practitioner rather than the pediatrician as a specialist.

LECTURES ON CLINICAL PSYCHIATRY. By Dr. EMIL KRAEPELIN, Professor of Psychiatry in the University of Munich. Authorized Translation from the Second German Edition. Revised and Edited by THOMAS JOHNSTONE, M.D., Edin., M.R.C.P., Lond. Member of the Medico-Psychological Association of Great Britain and Ireland. Second Edition. New York: William Wood & Company, 1906.

THE changes made in the second edition of this standard treatise on psychiatry consist chiefly in the substitution of more appropriate clinical histories for some of those used to illustrate the lectures at first. Some of the original cases which were found by later developments to be instances of some other disease than the one they were cited to exemplify, were dropped and some other more typical cases were made to take their places. Seven new cases are introduced to supplement the teaching regarding the insanity of degeneration. For the benefit of those not familiar with Kraepelin's work, it may be said that it is arranged in the form of clinical lectures, of which there are thirty-three in the book. This renders the book less adapted for use as a work of reference, but it makes it much easier of assimilation by the student who would ground himself thoroughly in psychiatry.

A COMPEND OF OPERATIVE GYNECOLOGY, Based on Lectures in the Course of Operative Gynecology on the Cadaver at the New York Post-Graduate Medical School and Hospital; delivered by WILLIAM SEAMAN BAINBRIDGE, M.D., Adjunct Professor of Operative Gynecology on the Cadaver, New York Post-Graduate Medical School and Hospital; Consulting Gynecologist, St. Mary's Hospital, Jamaica, L. I., Consulting Gynecologist to St. Andrew's Convalescent Hospital, New York, etc. Compiled, with additional notes, in collaboration with HAROLD D. MEEKER, M.D., Instructor in Operative Gynecology on the Cadaver, New York Post-Graduate Medical School and Hospital; Assistant, Department of Gynecology, Vanderbilt Clinic, College of Physicians and Surgeons, New York. New York: The Grafton Press, 1906.

THIS book is intended for students taking the course in Operative Gynecology on the Cadaver at the New York Post-Graduate Medical School. To such it should prove useful.

PRAESCRIPTIONES. Rezept-Taschenbuch für die Praxis. Von Dr. EMIL KANTOROWICZ, Arzt in Berlin. Mit einem Vorwort von Professor Dr. Senator. Berlin: August Hirschwald, 1906.

VERY nearly seventeen hundred prescriptions are contained in this formulary, conveniently arranged under the names of the conditions which they are intended to relieve. The collection is conspicuous for the comparatively small number of the newer remedies that are mentioned, and those that do appear for the most part belong to the minority that seems likely to remain permanently in the materia medica of the practitioner. As to this particular collection of prescriptions, in classic phrase: "For those who like this sort of thing, it is the sort of thing they like."

THE MORPHOLOGY OF NORMAL AND PATHOLOGICAL BLOOD. By GEORGE A. BUCKMASTER, D.M., Oxon., University College, London. Formerly Radcliffe Fellow, Magdalen College, Oxford. Philadelphia: P. Blakiston's Son & Co., 1906.

WHILE there has lately been no dearth of new books on hemology, the present volume is of a sort to prove useful to all students of the subject. Its substance is based on a course of lectures delivered in the Physiological Institute of the University of London, and there are accordingly more or less considerable gaps in continuity, but the book contains so much original work that it is of the greatest interest to the more advanced reader. Discussions of particular interest are the section relating to the polycythemia of high altitudes, which comprises the results of the author's own counts, made in Switzerland; the chapter on the significance of the blood platelets; and the one on the tests for blood. An opinion of the author's, expressed in several places, is that the enumeration of the red cells is of little value, owing to the errors likely to occur even in the most expert hands. Absolutely reliable results, he says, can be obtained only by using a selected pair of counters which are exact, counting the diluted blood on both of these, and rejecting any two determinations which do not agree within 10 per cent. The recent literature has been duly examined, and the author's opinions in regard to disputed points are always of a sort to command respect. The volume is a valuable contribution and may be warmly commended to those concerned in blood work.

ATMOKAUSIS UND ZESTOKAUSIS, die Behandlung mit hochgespantem Wasserdampf in der Gynäkologie. Von Dr. LUDWIG PINCUS, in Danzig. Zweite verbesserte Auflage. Wiesbaden: J. F. Bergmann, 1906.

IN this country comparatively little attention has been extended to a method of treatment which has found a number of advocates in Europe. It is now some twelve years ago that superheated steam was first used by Snerigew for checking obstinate uterine hemorrhage and in other conditions of this organ. The method was entirely empirical, however, and also fraught with considerable danger, until Pincus devised proper means for the application of both steam and hot air to the interior of the uterus, and also formulated the indications for their use, as well as working out the proper temperature and the length of time necessary for a proper working of the medium. The present volume, a book of almost four hundred pages, contains about all that we know about this method of treatment. We have to deal here with a procedure which may find some application in the hands of a specialist and an enthusiast, but for obvious reasons will probably never be universally adopted. The book is written in the involved style and language common to German text-books of the older school. Less verbosity and more concise practical descriptive matter would have added greatly to the value of the work.

A MANUAL AND ATLAS OF ORTHOPEDIC SURGERY. By JAMES K. YOUNG, M.D. Illustrated with over Seven Hundred Photographs and Line Drawings, mostly from Original Sources. Philadelphia: P. Blakiston's Son & Co., 1905.

THIS work is put forward by the author as the result of his studies and personal experiences during the past twenty years in the hospitals of Philadelphia and elsewhere, and he has included everything within the scope of orthopedics without invading the field of general surgery. The first part of the book, on general orthopedic surgery, includes an interesting chapter on the history of the science, and others on pathology, etiology, symptoms, diagnosis, and treatment, while the second part comprises chapters on the special types of deformity. The well-known position of Dr. Young in the specialty with which his name is associated assures us of excellent material in the text, and this same excellence is found in the illustrations, which are not only numerous but well selected. The only word of criticism is that directed to the size of the volume and its weight, which are sufficient to constitute a "bimanual" and we venture to say will interfere somewhat with its usefulness as a "ready" work of reference.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, Held at Cleveland, Ohio, May 30, 31, and June 1, 1906.

THE PRESIDENT, DR ALBERT VANDER VEER OF ALBANY, N. Y., IN THE CHAIR.

Surgery of the Large Intestine.—Dr. GEORGE E. ARMSTRONG of Montreal, Canada, said the death rate from cancer of the large intestine, as from cancer in other situations, was to be lowered by learning to recognize it in its early and incipient stage, rather than in devising heroic operative procedures. In addition to the usual indications of malignancy, as noted in the failing health and strength, attention was drawn to the fact that in a very large percentage of cases of early malignant disease of the intestine there was a regular daily rise of temperature amounting to two or more degrees, and it was pointed out that if this proved to be a general rule, it would perhaps be as valuable a sign of early malignant disease as of incipient tuberculosis. Another symptom-complex referred to was the frequently recurring colicky pains associated with constipation; and when the cancer is situated in the rectum, to the sudden development of hemorrhoids with constipation in a patient who was previously regular. The harmless form of hemorrhoids usually developed as the result of prolonged and persistent constipation. The importance of a very thorough and careful examination was referred to, and in particular a careful search for the presence of tumor mass, the examination not being considered complete until carried out with the patient in varying positions, as a distinguishing feature of these tumors was their mobility. The treatment of these cases was discussed from two points of view. (1) The relief of intestinal obstruction. (2) The radical removal of the growth. In the former it was pointed out that good judgment had more to do with the results than manual dexterity or knowledge of technique, and it was urged that in patients admitted to hospital with distended abdomen, stercoraceous vomiting, general peritonitis, and intestinal walls sodden and friable, nothing more should be attempted than drainage of the bowel through the appendix or an appropriately placed Paul tube. Many deaths occurred through trying to do too much under such circumstances. Ideal surgery should not be considered; it was a question of expedience and of temporizing, and of giving a patient time to recover from the toxemia present. Short circuiting of the growth, and its removal at the same or some subsequent time was commended as a cleaner and more satisfactory procedure than colostomy, and as a method which offered opportunity for removal of glands. In speaking of cancer of the rectum (the so-called high cancer of the rectum), a finger length from the anus, different methods were referred to. The perineal route for the removal of high cancer of the rectum was condemned, as giving insufficient access, either for the proper control of hemorrhage or the removal of the disease and glands. The combined abdominal and perineal method was advocated as the most conservative, the safest, and most radical of the methods so far employed. Through the abdominal incision the operator could get as far above the disease as necessary. The glands might be thoroughly removed and involvement of the peritoneum or bladder, if present, might be recognized and dealt with as might seem best. The greater part of the operative work might be accomplished before the intestine was opened or the peritoneum exposed to infection. If there was sufficient of the lower end left after the removal of the disease, the intestinal canal might be restored by a sigmoidorectostomy, or an ileosigmoidostomy, and it went without saying that the canal should be restored whenever possible. If this was impossible, the upper end might be brought out through a colotomy wound, and a permanent artificial anus established. The lower end could then be separated by blunt dissection, pushed down behind the bladder, and the peritoneum closed over it much in the same way as after extirpation of the uterus. The lower end might then be removed by the perineal route. If the patient's condition was not good, the removal of the lower end of the rectum might be delayed for a few days, but in the four cases in which the author had removed high rectal disease by this method the patients had been remarkably free from shock, and had left the table in good condition. It was pointed out that the artificial anus in front, while possibly causing more mental distress than one situated behind, was more easily cleaned and looked after, and made the patient more independent of nurse or valet. The more frequent use of the Paul tube in colotomies was advocated.

Cancer of the Sigmoid and Rectum.—Dr. CHARLES H. MAYO of Rochester, Minn., said that with some modifications the curability of cancer was generally accepted. The disease was more rapidly disseminated in the young from their active lymphatics. The large bowel was the natural drier or absorber of fluids, but had a limited lymph drainage. Cancer of the colon was a disease in a removable structure which might remain essentially local for a long period. In the sigmoid, if the tumor was not removable, short circuiting the bowel was advisable. Low cancer of the rectum could be removed by the perineal route. Those cases which were above easy reach were best removed by a combined operation, abdominal and perineal. If the muscular and nerve tissue could be preserved, the anal outlet was maintained; if it must be destroyed, an inguinal anus was made. If within (easy) reach and inoperable, curetting and cautery were preferable to colostomy. In five years Drs. W. J. and C. H. Mayo (usually working together) had operated upon twenty-six patients by the combined method; seven died from the operation or within one month; ten cases operated too recently to be of value, but alive and well; seven lived over one year, five alive now; five lived over two years, three alive now; three lived over three years, two alive now. The results of cure were favorable, although the operative mortality was high.

Cancer of the Colon, with Special Reference to Its Diagnosis: Types of Operation: Method of Avoiding Fecal Drowning.—Dr. WILLY MEYER of New York explained that his remarks would have reference to that part of the colon only which was situated between cecum and sigmoid. He pointed out the paramount importance of early diagnosis and timely operation, at the same time admitting the great difficulty in reaching such a consummation, chiefly on account of the usually latent development of the disease. He cited a case in which the patient had been apparently in perfect health up to within a few weeks of his death. The symptoms then developing pointed to malignant tumor of the anterior mediastinum. Postmortem showed primary carcinoma of the colon at the splenic curvature, with metastatic involvement of the mediastinum. Every symptom, therefore, he stated, that justified the suspicion of colonic cancer, and every method that might help to determine the correctness or incorrectness of such a suspicion, must be welcome; all the more, as the prognosis of cancer of the colon was better than that of malignant disease in any other part of the gastrointestinal tract. Of the subjective symptoms, he considered of greatest value that of periodic, not always painful, contraction within the abdomen, so often noticed by the patient. It occurred usually in more or less the same locality, and, in an advanced stage of the disease, was frequently followed by a distinctly audible gurgling sound. He called this sign "subjective stiffening of the gut, in contradistinction to the "objective stiffening" or tetanic recurrent per-

istalsis of the gut proximal to the seat of the disease, first described by Nothnagel as a visible and palpable sign. In one of his own cases, a carcinoma of the transverse colon, this "subjective stiffening" of the gut represented the only symptom complained of during many months. Among the objective signs, the author mentioned the appearance of a palpable tumor in 40 per cent. of the cases only, chronic circumscribed meteorism, the objective stiffening of the gut, above referred to, and the rather sudden formation of capillary angiomata and pigmented warts in the skin of the abdominal wall. The latter he considered an unfailing pathognomonic sign of cancer of the colon, provided the history and palpation pointed to this disease. Dr. Meyer had personally observed this phenomenon in four of his cases. With regard to differential diagnosis, the following conditions came principally into consideration: (1) Tumor of the kidney, or floating kidney. (2) Chronic cholecystitis or hydrops of the gall-bladder. (3) Retroperitoneal infiltrated lymphatic glands corresponding to the location of the splenic flexure, eventually secondary to a cancer of the pancreas. (4) Benign intracolonic sessile tumors. He believed the age of the patient to be no contraindication to radical operation, so long as his general condition was still good. In greatly debilitated patients, palliative operation only could, of course, be performed, but, if done at an early stage of the disease, the objectionable artificial anus, otherwise unavoidable, might be obviated by way of a lateral anastomosis. In discussing the different operations indicated for the various conditions found, Dr. Meyer pointed out the danger from the so-called "fecal drowning," which heretofore had been the *bête noir* of the surgeon, whenever more aggressive work was decided upon. He called attention to and demonstrated Kausch's esophageal narcosis tube, an apparatus designed for the purpose of overcoming this danger. The author stated that his personal operative experience with cancer of the colon within the section limited by his paper covered eleven cases, but that so far he had not had an opportunity of employing the narcosis tube just described. He added a brief record of his cases, all of which, with the exception of one, came under his care in a well-nigh hopeless condition.

The Surgery of Tuberculosis of the Colon.—Dr. L. L. McArthur of Chicago read a paper on this subject, in which he submitted the following propositions: (1) Intestinal tuberculosis was far more frequent than had been in the past accepted. (2) Its primary nature in this situation was now admitted to be 5 per cent. by the pathologists, who also claimed that 25 per cent. of all human tuberculosis gained its entrance through the intestinal mucosa. (3) Either the "ulcerative" or the "hypertrophic" type of this disease was (at some time) amenable to surgical interference. (4) That interference should be either by excision or exclusion. (5) That surgical insult in these forms of intestinal disease was better borne than a like degree in any other. (6) That early recognition by the internist and interference by the surgeon would eliminate a large proportion of cases now classified as tabes mesenterica. Tuberculosis manifested itself in the intestine in two forms, the ulcerative and the hypertrophic. Individuals extremely prostrated with this affection were tolerant to extensive surgical insults, which in other ailments requiring similar surgical procedures proved fatal. Both of these varieties in his experience were amenable at times to surgery, the nature of which interference must be determined by the individual case. So many factors would take part in its determination that no set rule could be laid down. Practically, its surgery divided itself into either exclusion or excision, the choice being determined by the conditions obtaining in the given case. The exclusion might be partial or total. The term "partial" he applied to a side to side anastomosis of the intestinal tube above and below the diseased area, while a "total" exclusion implied a resection of the bowel wall above the disease, closure of the distal end, with implantation of the proximal end well below the diseased area. It was distinctly to be understood that absolute occlusion was never practised. Though the number of cases of tuberculosis of the large intestine demanding surgical interference in his practice had been limited, the regularity with which they had recovered had made him most hopeful for the future. He presented from his records cases upon which he had operated, illustrating the points he emphasized in his paper.

Myomata of the Large Intestine.—Dr. W. L. Estes of South Bethlehem, Pa., said that true myomata of the large intestine were almost unknown. So-called myomata of the large intestines were histologically fibromyomata and they were practically always fibroleiomyomata. The rectum was the part of the large intestine which in the great majority of the cases was involved, although there were a few cases on record of myomata of the cecum, of the ascending and of the descending colon. Dr. E. Lexner, of von Bergmann's clinic, had classified myomata, and he had collected the largest number of cases the writer had seen. Lexner made three groups of these tumors, as follows: (1) Tumors which grew in the lumen of the gut. These appeared as pedunculated, roundish, or polyp-like tumors, of rather hard consistency, covered by mucous membrane. They might be removed by way of the anus. The pedicles should be ligated and then cut through. (2) Tumors which grew by a pedicle from the outside walls of the intestine, and which by their bulk impinged upon and might produce almost complete stenosis of the gut by their gradually increasing pressure. This class might involve any part of the large intestine, but were chiefly found in the upper part of the rectum. These tumors required a laparotomy for their removal. (3) Tumors which grew from the rear of the rectum and which, by their bulk, pushed the rectum forward and filled up the cavity of the pelvis. These tumors were easily mistaken for ovarian, and other common tumors of the pelvis. They required sacral exsections or parasacral incisions for their removal. The writer suggested the possibility of another, or fourth, group. Tumors in this class resulted from inflammations. While they were really hyperplasias, they might, but very rarely, develop as circumscribed masses in the walls of the gut, which by persistent hypertrophic thickening might cause stenosis of the gut. The sigmoid flexure was the part of the large intestine involved by this class of tumors. The writer gave the history of a very remarkable case of stenosis of the sigmoid flexure, which resulted from enormous and symmetrical hyperplasia, chiefly of the muscular coats of the gut, and which formed a well-marked tumor of the intestine. The intestine was strictured, almost entirely closed, within the area of the tumor, not above it, nor below it, and the stenosis was produced by the bulk of the hyperplastic muscular layer. Histologically, it was classed by the pathologist as a myofibroma. The writer had not been able to find any mention in surgical or pathological literature of a case similar to his. He believed, therefore, that his case was very rare, and that it indicated the possibility of a fourth class of tumor of the large intestine, which belonged to the myomatous groups. These tumors required a laparotomy for their removal. On account of the very numerous and dense adhesions, the operation for their removal was an extremely tedious and difficult one.

The Surgery of Carcinoma of the Upper Portion of the Rectum and the Sigmoid Colon, with Special Reference to the Combined Sacral and Abdominal Operation for the Resection of These Tumors.—Dr. Jos. C. Bloodgood of Baltimore, Md., stated that sufficient time had elapsed to clearly demonstrate that resection had accomplished a certain number of cures for carcinoma of the stomach, small and large intestines. In the majority of these cases the hope of future progress depended more upon earlier recognition than upon improvement in opera-

tive technique. The technique of gastrectomy for carcinoma was most satisfactory. The only partially settled problem was in regard to the extent to which glandular dissection should be carried. At the present time the majority of authorities favored a restricted glandular operation in view of the higher mortality of the more extensive dissection and the slight probability of a cure if these more remote glands were involved. With carcinoma of the small intestine there was not sufficient experience to formulate positive deductions. Malignant epithelial tumors from the ileocecal valve to the anus were comparatively of frequent occurrence. When the tumor was situated in that part of the large intestine above the promontory of the sacrum the entire operative manipulation was performed within the abdomen. These tumors which arose from the mucous membrane of the large intestine showed little tendency to extend beyond the peritoneal coat, except at the mesenteric border. Adhesions due to the infiltration of the epithelial growth through the peritoneal coat to neighboring viscera were late complications. In planning for the complete extirpation of these growths one should resect a very generous portion of the apparently uninvolved intestine on each side of the palpable tumor, because infiltration of the new growth along the submucosa beyond the open ulcer was a common occurrence. The next most important step was to include with this portion of the bowel a large area of mesocolon, whether the glands were palpable or not. In selecting the point for the division of the bowel above and below the tumor one should have in mind not only the complete removal of the tumor, but to select a point for division which should have, after the resection of the mesenteric area, a proper blood supply. The experience of any surgical clinic and the literature showed a comparatively large number of cases in which the tumor had every appearance of curability, but in which an operative death due to gangrene of one or both ends of the resected intestine marred the result. The decision as to the method of suture after the resection was a somewhat difficult one. As a rule, closure of the two ends with a lateral anastomosis was the safer procedure. In approaching his cases, since 1904, he had endeavored not only to fulfill the requirements of a complete removal of the malignant disease, but to attempt, after its removal, a restoration of the continuity of the bowel by an end to end anastomosis. In his first case, in November, 1904, he was able to perform the complete resection of a carcinoma situated just above the promontory of the sacrum entirely within the abdomen. The condition of the patient, however, forbade at that time an attempt at suture. At the present writing, eighteen months since operation, the patient was content with the colostomy. In a second case, in July, 1905, it was necessary to finish the resection through a sacral incision. In this instance it was possible to save, with a good blood supply, eight inches of the lower end of the rectum, which rendered an end to end suture in the sacral wound possible. The result at the present time is unusually satisfactory. In the third and most recent case it was possible to resect and suture entirely within the abdomen. A careful study of the cases in the literature would justify the following criticisms: (1) Colostomy had been performed too frequently as a primary operation. He believed that colostomy was not indicated unless the patients were first seen in the condition of an acute obstruction, or their condition was so critical from chronic obstruction that a prolonged operation was contraindicated. If possible, the entire operation should be performed at one sitting. (2) It was unnecessary to ligate the vessels so far from the mesenteric border of the colon. Resection of the glands up to this point was not indicated. If they were involved, his experience demonstrated that the condition was hopeless for an ultimate cure. The disadvantage of ligation of the vessels so far from the colon was due to the fact that, after such a ligation, a more extensive resection of large intestine was necessary in order to leave bowel with proper circulation. (3) Too much bowel below the tumor was removed. If one restricted the resection of the large intestine above and below the growth to that necessary only for the complete removal of the disease, and ligated vessels as they were met in the proper dissection of the mesentery with its glands and the fat between the rectum and the sacrum, it would be possible in a large number of cases to restore the continuity of the bowel by an end to end suture. The pathological examination of a number of specimens and the zone of mesenteric involvement which he had made apparently confirmed the statements in the previous paragraphs. That was, in this somewhat restricted operation the new growth was given sufficient margin and at the same time the circulation of the remaining portion was not impaired, and in the majority of cases restoration of continuity.

A Series of Cases of Malignant Growths, with a Clinical Study of the Possibilities of Carcinoma and Sarcoma Appearing in the Same Patient.—This was the title of dent's Address, delivered by Dr. Albert Vander Veer of Albany, N. Y., which was a departure from the usual historical review of the progress of surgery. For many years he had had in mind the possibility of the duality of malignant diseases, that is, as to carcinoma and sarcoma presenting in the same patient, and as to the genesis of many cases appearing in the same family. With these thoughts in mind, he presented the following observations: He was first attracted to this subject by the case of Mrs. P. R., aet. 57, who presented herself March 20, 1870, with acute carcinoma of the left breast, and who, while being prepared for operation, was suddenly seized with a convulsion, ending in immediate death. An autopsy revealed a tumor from the dura, extending outward, ulcerating nearly through the cranium, and which caused deep pressure upon the brain substance. At autopsy no other growths were found in the brain, and, aside from the left breast, all other organs were in a healthy condition. A microscopical examination made of the brain tumor at the time, together with the microscopical appearances, classed it as a sarcoma. The microscopical examination of the tumor from the breast was positively that of acute scirrhus or carcinoma. Years passed by and though many cases were observed, giving all the phases of malignant growths, yet no picture presented itself like that carried in his mind of carcinoma and sarcoma appearing in the same individual. He then described in detail four cases of carcinoma of the breast occurring in four sisters, and considered their connections with several other cases of malignant disease in other members of the same family. In the study of these cases the thought of house infection was to be considered. The first two sisters were born in the house where the uncle passed much of his time, when suffering from malignant growth of the foot. The last two were born in the house and lived where the father was attacked with epithelioma of the lip and face, and was ill for a long time. Each of the houses referred to was old at the time of the birth of these children. One is yet standing, but in neither has he been able to learn of any more or other cases of malignancy. It was somewhat interesting to note that of the four sisters it was the left breast that was implicated in each case. The writer had a record of and had seen a number of cases of carcinoma of the breast in females who had non-malignant fibroids of the uterus, and in operating for the former malignancy did not develop in the latter. He had also operated for both conditions, when the strength of the patient would admit, always bearing in mind the sympathy between these organs in malignancy of either. As far as possible, the writer had looked up the literature, which was exceedingly meagre, bearing on the subject of this paper, and presented extracts (having in mind the etiology, pathology, and possible prophylaxis)

from the admirable work of Prof. Jensen of Copenhagen, to whom was awarded the Walker prize by the Royal College of Physicians and Surgeons.

Some Experiences in Intracranial Surgery.—Mr. Charles A. Ballance of London, England, said that surgical intervention was, at present, the only remedy for certain intracranial diseases, but only too generally the same apathy prevailed in adopting this remedy as was prevalent some twenty-five years ago in operating for analogous diseases in the abdomen. He offered some remarks suggested by his own experience in operating for tumor of the brain, abscess of the brain, subdural hematocele, meningitis and hydrocephalus interna.

Tumor.—Prominent among the obstacles to successful operation for intracranial disease, and particularly for brain tumor, was the difficulty of making a precise diagnosis at an early stage of the disease. The diagnosis of intracranial disease was, speaking generally, a far more complex problem than that of intraabdominal disease, and, moreover, within the skull an exploratory operation could be conducted in the same rapid and complete manner and with as little serious risk as in the abdomen. The maxim that diagnosis must precede operation was true only of those diseases, the signs, symptoms and course of which were fully comprehended. When the early clinical manifestations of a disease were ill-understood and when danger attended delay, the surgeon was content to act upon a provisional diagnosis. Many lives were thus saved and diagnosis became perfected. Another point of practical interest was that a highly cellular tumor of the brain was not necessarily very malignant. This was true not of brain tumors only, but of tumors of other parts of the body, thus a large cellular carcinoma mammæ might prove less malignant than a small atrophic scirrhus with few cellular elements. In 1903 he drained a large gliomatous cyst in the left frontal lobe of a man under the care of Sir William Gowers. The symptoms were relieved, but recurred two years later. He then removed a large mass of tumor from the same region. The patient left the hospital well and proposed to resume his work. There was one point to which he drew attention, namely, the bulging of the occipital fossa in cerebellar tumor in childhood. In 1889 he removed a tumor from the cerebellum of a child, aged three and one-half years. The main localizing sign was a bulging occipital fossa. To prove that operation for cerebellar tumor in the adult might be completely successful, he mentioned that, in 1894, he removed an encapsulated fibrosarcoma from the right cerebellar fossa of a woman, aged forty-nine years, and she was alive and well now.

Abscess.—It was now generally recognized that an abscess in the brain should be treated like an abscess elsewhere. In most cases of slowly spreading infection from chronic disease adhesions occurred at the site of infection, binding together dura, arachnoid, pia, and cortex.

Subdural Hematocele.—Satisfactory results were obtained by removing such cysts. In a case of his, already published, a cyst, 7 by 4½ by 1½ inches, was successfully removed. He had since met with three other cases. In one of Prescott Hewitt's cases the patient, a boy, received a blow on the head from a cricket ball. He lived for fifteen years, during which time he suffered from intermittent insanity.

Meningitis.—He made some remarks about meningitis serosa, a condition which often arose when pus collected outside the dura, as, for example, in some cases of acute mastoid suppuration. The symptoms were: Rise of temperature, slowing of pulse, sluggish pulse, sickness and drowsiness. All these symptoms might be promptly relieved by lumbar puncture. The withdrawal of fluid might prevent the meningitis going on to suppuration, just as the removal of fluid from the pleura by the aspirator relieved the lung from pressure and might prevent the pleurisy going on to empyema.

Hydrocephalus was met with in infants as a congenital condition or as the result of posterior basal meningitis; the congenital form had resulted from intrauterine meningitis. There were two methods of dealing with hydrocephalus. (1) Intradural drainage. This could be carried out through the lateral angle of the anterior fontanelle, or the descending cornu of the lateral ventricle on the right side might be opened by the ingenious method of Keen. A fine tube, bent at a right angle, made of gold and iridium, or of pure platinum, should be used. (2) Ligature of both carotids. The secretion of fluid might be lessened by ligature of one or both common carotid arteries. This could safely be done in hydrocephalic infants, in whom the blood supply to the brain stem was of much more relative importance than that to the cerebral substance and the choroid plexus. He had had successful cases by both these methods.

Tuberculous Meningitis.—He had published a case in which the removal of tuberculous disease of the temporal bone cured commencing infection of the meninges, as evidenced by headache, vomiting and squint. He was convinced that the treatment of intracranial disease had been too long encrusted with conventionality. Cases of brain disease requiring surgical relief were numerous and widely distributed, but those who operated on them, especially on brain tumors, were few and far between. Not so long ago the same was true of acute abdominal diseases, but now the surgery of acute abdominal disease was successfully practised by the great body of surgeons. Until this stage in the history of brain tumors had been reached many remediable cases must go unrelieved.

A Year's Experience in Intestinal Surgery.—Dr. John B. Deaver of Philadelphia, Pa., said the forty patients whose cases formed the text of his remarks were operated on at the German Hospital and the Children's Hospital of the Mary J. Drexel Home since January 1, 1905. These cases comprised twelve simple enteroenterostomies; eleven intestinal resections, with enteroenterostomy; one enterotomy; two colostomies; seven enterorraphies for various forms of fecal fistula; one suture of a typhoid perforation; one reduction by manipulation of an intussusception; and eight instances in which strangulating bands or adhesions were divided, besides three other (atypical) operations—a total of forty-six operations on forty patients. There were 13 cases of intestinal carcinoma, all in the large bowel. The cecum was dissected in four cases, the hepatic flexure of the colon in two, and there was one case each in which the part affected was the transverse colon, the splenic flexure of the colon, and the rectum; while there were four patients in whom the sigmoid was the seat of malignant disease. Five of these thirteen patients died—those patients in whom the splenic flexure and the rectum were involved; one of those with the cecum affected, and two of those in whom the sigmoid flexure was diseased. The remaining eight patients recovered from the primary operation, and were relieved temporarily, but of the four successful cases in which the patients were seen sufficiently early for a radical operation to be done, two developed symptoms of recurrence about eight months later, and were again temporarily relieved by further operation, and in the case of two others, on whom a radical operation was done, sufficient time had not elapsed since the operation to permit of their being considered in this connection.

Treatment of Congenital Dislocation of the Hip.—Dr. E. H. Bradford of Boston said that in a large number of cases of congenital dislocation of the hip complete cure could be accomplished by manipulative reduction. In difficult cases efficient mechanical reduction was of assistance. In certain cases, owing to a distorted capsule, the femoral head was not placed deep in the acetabulum or was kept

from the bottom of the acetabulum by a capsular fold and relapse took place. Under these circumstances the surgeon could by incision of the capsule widen the capsular constriction, place the capsular flaps around the head and neck, secure the head of the femur until cicatrization had formed a retaining capsule about the reduced head. The operation was a somewhat difficult one and was easily imperfectly done. It was a serious one, but was capable of giving most satisfactory results in cases where failure or imperfect result was otherwise inevitable. It was manifest that in a relaxed capsule much depended on the after-treatment. If the capsule was loose, the head would drop out if not held in place until the tissues had become reformed, so that they held the head firmly. A certain number of relapses were due to this. From the experience at the Boston Children's Hospital it appeared that the position of the limb after reduction and the after-treatment depended largely upon the anatomical condition of the joint and whether there was a strong projecting acetabular lip. Within this was a zona orbicularis, and precise rules could not be laid down further than that the head should be placed well in the socket and kept there until it was firm in its improved position and not kept long enough in a distorted position for the tissues to become too stiff or non-elastic. If the head was not properly reduced, it was inadvisable in the hope of benefit from delay to postpone attempts at other measures of relief, *i.e.* incision or a repeated manipulation.

The Open Treatment of Fractures.—Dr. Edward Martin of Philadelphia said that the wounds necessitated by the open treatment of fracture were more prone to suppurate than were those made in the performance of other operations. This partly because foreign bodies, often of considerable size, were buried in the wound, but mainly because as a result of prolonged manipulation and rough handling and the use of tools ill-adapted to the purpose there was left at the end of operation a large amount of tissue so hopelessly devitalized that an abundant culture material was provided for even the slight infection which inevitably took place during the course of the most carefully conducted operation. Of the many ingenious devices employed for permanently fixing broken bone ends in their proper relation to each other, chromicized catgut, wire, screws, and silver plates were the most serviceable. If the surgeon could be assured of a perfectly sterile No. 3 catgut so largely deprived of chromic acid as not to prove irritating to the tissues, this would be the material of choice in all cases where suture or encircling ligature was applicable. Screws were extremely serviceable in that they represented foreign bodies of moderate size, were readily applied and would often hold bones in perfect apposition. They were especially applicable to the repair of oblique fractures of long bones. In fractures of the extremities of these bones the cancellous tissue gave a grip so feeble as to make their use of little service unless driven through and through. The proper application of a screw implied the selection of an almost cylindrical instrument with a deep thread cut clear to the head, and of such length as to pass completely through the bone at right angles to the line of fracture, but not beyond. Screws selected from the carpenter's tool box and the majority of those sold by surgical instrument makers were ill-adapted to the purposes of bone surgery, since the thread was lacking where it was most useful and the pronounced conical shape greatly and uselessly increased the difficulty of driving the screw home. The silver plate found its most useful application in transverse fractures. Its proper fitting was made easy by the use of grasping instruments which not only held the two bones in accurate apposition one with the other, but also secured the plate firmly in place while the holes were being bored and the screws applied. The starting of the screws in the drill holes, particularly in the treatment of broken small bones, such as the ulna, clavicle or fibula, or when the fragments to be held in apposition lay at the bottom of a deep wound, was greatly facilitated by a screw driver which firmly held, in a jaw devised for the purpose, the screw until it was fixed in its drill hole. Such an instrument he exhibited. The open treatment of simple fracture should not be regarded as an emergency operation, and considering the fact that, for instance, nine out of every ten adults who sustained a fracture of the shaft of the femur exhibited as a result of conservative treatment permanent deformity and crippling, it would seem desirable to practice formal operation more frequently than is now done.

Some Experiences in the Operation of Thyroidectomy. Partial and Complete.—Dr. Francis J. Shepherd of Montreal said his first operation was in 1883. In the first twenty-five cases he operated upon he employed the method of Socin, viz., enucleation, but, meeting with two severe cases of secondary hemorrhage, he gave up this method in the larger tumors for excision. In speaking of the re lation of the recurrrent laryngeal nerve to this operation, he stated that only once in about one hundred operations had he wounded the laryngeal nerve. He mentioned that paralysis of one nerve due to pressure of the tumor was quite common, and in his experience it was on the side opposite to that of the largest development of the tumor. He dwelt on the importance of having the larynx examined before operation, for if one cord was found paralyzed the operator would necessarily be more careful of the other. The amount of hemorrhage during operation might be considerable and it was waste of time to try and secure the bleeding points, for the bleeding veins were very friable. In cases of free bleeding he rapidly turned out the whole tumor and secured the superior and inferior thyroid arteries. He had met with several cases of anomalous gland, where the upper cornua almost met behind, surrounding the trachea and esophagus, and one case where the gland grew between the trachea and esophagus. The indications for operation in simple goitre, the operator considered to be as follows: (1) Progressively increasing size of the tumor. (2) Rapid growth, with dyspnea. (3) Narrowing of the trachea. (4) Difficulty in swallowing. (5) Alteration of the voice. (6) Tachycardia and increasing nervousness. (7) Inconvenience and deformity, due to the size of the tumor. As regards anesthesia, Dr. Shepherd stated that he always used general anesthesia. He commenced with chloroform, then took up ether, and now used equal parts of ether and chloroform. So far he had had no death and no alarming symptoms. He thought the dangers from general anesthesia had been much exaggerated and that in a few years more thyroidectomies would be performed under general anesthesia than at present. He had operated in seven malignant cases, with one permanent recovery, and agreed with Bloodgood that where carcinoma infiltrated no cure followed extirpation. He had had no deaths in simple goiters, though he had had two following operation in exophthalmic goiter. In operating, Dr. Shepherd preferred the straight incision internal to the sternomastoid, and he tied the superior thyroid before turning out the gland; then the inferior thyroid and recurrent nerve were looked for and identified. After operation he used a drainage tube for twenty-four hours, sometimes if there had been much oozing he packed with iodoform gauze. High temperature occurred after operation in 60 to 80 per cent. He had seen only one case of myxedema following extirpation of the gland, and this was in a case of malignant disease. The dangers of operation were stated to be: Shock, hemorrhage, injury to the recurrent nerves, infection, pneumonia, heart failure, etc. In only one case had tracheotomy to be performed. As he intended reading another paper on the surgical treatment of exophthalmic goiter, this subject would not be considered.

A New Method of Utilization of the Sac in the Radical Cure of Hernia.—Dr. Roswell Park of Buffalo said the

method consisted simply in utilizing what was usually entirely dissected away, namely, the sac, and in making of it the suture material with which the canal itself was closed. Briefly, the procedure was as follows, especially with inguinal hernia: To isolate the sac, then to empty it, and to clean it of all superficial fat. It was thus separated from the cord and made to appear as a distinct separate structure up to the level of the internal ring. His usual procedure for many years had been to penetrate the abdominal aponeurosis at a point opposite the internal ring, with forceps made for the purpose with alligator jaw, although these were not at all essential. The forceps introduced through this opening was made to appear lower in the inguinal canal, and here to seize the sac and, in the act of withdrawal, pull it after it, and thus bring it out at the punctured point. Here he used to twist the sac, ligate the neck, and tack it in place with one or two chromicized sutures. He had now modified the procedure in such a way that instead of cutting off the sac outside the point where it was fastened, he utilized it as a band of suture material, with which a coarse but strong suture was made, binding together the lateral margins of the inguinal canal. The advantages of this method were: (1) It afforded almost as perfect and complete a method of closure of the inguinal canal as did any other. (2) It utilized a portion of this sac which would otherwise be quite discarded and substituted fresh animal suture of the patient's own tissue for foreign animal material, while, at the same time, under ordinary circumstances, its sterility might be guaranteed. (3) While he had not had opportunity to demonstrate the fact, he thought it fair to assume that such tissue so used did not disappear by absorption, as would tendon or other foreign material, but rather was organized and served as an additional means of strength and security, forming, as it were, a series of bridges or transverse fastenings by which the obliteration of the inguinal canal should be more securely attained. He had not yet been able to resort to this procedure in a large number of cases, but in those in which he had so far used it it had given very satisfactory results.

The Use of Thyroid Extract to Shorten the Coagulation Time of the Blood.—Dr. William J. Taylor of Philadelphia advised that it be used in cases of hemophiliacs where surgical operation was demanded, or where they had received any accidental wound, and also in patients whose blood had been altered by disease. He stated that normal blood was not affected in any way by the use of thyroid extract, even where its use had produced distinct constitutional effects; that it acted only upon blood which lacked fibrin ferment. He mentioned the fact that A. E. Wright had found that the coagulation time of the blood was lengthened by starvation and shortened immediately after a hearty meal, and the efficiency of the action of calcium chloride was increased by combining it with an albuminous substance, such as an aqueous extract of thymus, thyroid, testicle, gastric, and other mucous membrane. He cited three cases of bleeders in which thyroid extract was used with marked benefit, and mentioned one instance in which it was used in a case of profound jaundice due to obstruction of the hepatic duct. He recommended that in all cases of suspected or probably delayed coagulation time that the blood should be carefully tested, and that the dried thyroid extract should be given in three grain doses in capsules three times a day, and stated also that it had been used with very great effect in several cases of purpura with spongy and bleeding gums, occurring during the course of typhoid fever.

Hyperplastic Tuberculosis of the Intestines and Peritoneum.—Dr. Charles B. Nancrede of Ann Arbor, Mich., put on record another instance of that rare manifestation of tuberculosis in the intestinal tract, the hyperplastic form, instances of which had been reported during the past fifteen or eighteen years. He gave a brief historical account of the cases reported by various authors. Treatment resolved itself into excision of the affected portion of the bowel. Doubtless fresh air, sunshine, tonics, and the ordinary measures addressed to the treatment of tuberculosis located elsewhere might serve as roborants and increase the peritoneal tissue resistance, as well as that of other parts, but no direct benefit could be expected, as was the case in certain instances of ordinary tuberculous peritonitis.

A Review of 1,500 Operations Upon the Gall-Bladder and Bile Passages, with Especial Reference to the Mortality.—Dr. William J. Mayo of Rochester, Minn., said the mortality in 1,500 operations was 4.4 per cent. In the last series of 500 it was 3.2 per cent. Every operated case dying in the hospital without regard to time or cause of death was counted as an operative mortality. Of operations for uncomplicated gallstone disease, the mortality, 1-3 of 1 per cent., was due to accidental causes. Complications the result of delay caused more than 9-10 of the death rate; 95 per cent. of all complications occurred in patients who had had marked evidences of gallstone disease and ample period of good health for safe operation. The now recognized necessity for early operation in appendicitis was due to the former high mortality attending secondary abdominal complications. The same reasons held good for early operation in gallstone disease, only it was involvement of liver ducts instead of peritoneum which gave fatal complications. Of 845 cholecystostomies, the mortality was 2.13 per cent. In the last series of 500, it was 1.47 per cent. Of 319 cholecystectomies, the mortality was 3.13 per cent. In the last series of 500 it was 1.62 per cent. The operation was indicated in all cases in which the gall-bladder had lost its function, especially in cystic duct obstructions and for malignant disease. It was a slightly more serious operation than cholecystostomy, but had a growing field of usefulness in all cases in which the gall-bladder was involved. Common duct operations, 207 cases. Group I—105 cases; 3 deaths; 2.9 per cent. Consisting of those cases having gallstones in the common duct, operated during the quiescent period; jaundice and infection moderate. Group II—61 cases; 10 deaths; 16 per cent.; in which there was active infection involving the ducts of the liver, and jaundice. Patients suffered from Charcot's fever (fever and ague type). Obstruction was severe, but not continually complete. Group III—29 cases; 10 deaths; 34 per cent. Complete obstruction of common duct in which no bile passes into the intestinal canal, elimination taking place by means of the kidneys and skin. Group IV—Malignant disease; 12 cases; 4 deaths; 33 1-3 per cent. Gallstone present in nearly all. Pancreas involved in 86 out of the 1,500 cases; 4 acute, with 2 deaths; 6 subacute, with 1 death; 9 cancer, with 5 deaths; 67 chronic, without marked effect on the mortality.

The Serum-Therapy of Tetanus.—Dr. C. A. Porter of Boston emphasized the rational use of serum in acute or severe subacute tetanus. While some of the details upon which it had been founded might subsequently require changing, such a consistent method of attacking tetanus toxins, resting in the main upon well-founded experiments, had the merits of simplicity. In carrying out this treatment one should picture to himself the toxins traveling along the motor nerves of the affected part, even upward toward the higher motor ganglia, and also by absorption through the lymphatics, entering the general blood current, to be brought directly to the central ganglia through the motor nerve endings of the rest of the skeletal muscles. Antitoxin, to be effective, must reach the poison before it had entered the motor tract, or must by direct injection into the tissues immunize them in anticipation of the arrival of the aftercoming toxin, or neutralize it locally before a stable compound had been formed. In the treatment he recommended the following: (1) Immediate intravenous and subcutaneous injections to neutralize the circulating toxin. (2) Immunizing or neutralizing injections at the

highest level which the severity of the symptoms appeared to justify; directly into the cord, as advocated by Rogers, or into the higher motor nerves, such as the hypoglossal and spinal accessory, as suggested by the author. (3) Peripheral intraneural injections as near to the cord as possible. Where amputation was indicated or allowed, there was positive experimental evidence that nerve section would isolate the toxins in the limb. (4) Lymphatic absorption would be diminished by the application of Bier's principle of passive hyperemia, or by circumcision of the limb. (5) Parenchymatous injections, especially into the muscles, might be of distinct value in addition to subcutaneous and intravenous injections. (6) If possible, the local focus should be thoroughly eradicated. (7) We had no right to neglect symptomatic treatment. (8) When once the disease had progressed beyond a certain stage, animal experimentation gave us no ground for hope that any treatment whatever could be successful.

The Treatment of Tetanus by Magnesium Sulphate.—Dr. Joseph A. Blake of New York said that from his experience in human tetanus intraspinal injections relieved spasm, so it must be inferred that they produced a block of nerve impulses by direct action on the nerve trunks. So far its employment in human tetanus had not been attended by uniform results. This might be due to different degrees of susceptibility on part of the patient, and partly by variations in technique, or lack of experience in the use of magnesium sulphate, on the part of the medical attendant. So far as he could ascertain, only four cases of tetanus had been treated with magnesium sulphate. Of this number only one recovered, and this was his own case. His case was one of acute tetanus in a boy of fifteen. The injections controlled the convulsions in this patient for periods varying from twenty-nine to thirty-seven hours each. His impression of this drug was that although we could not be certain of its effect, yet it was reasonably safe and offered a means of modifying the convulsions and relieving pain in a way no other drug had approached.

The Present Status of Our Knowledge of the Serum Therapy of Surgical Affections.—Dr. Charles A. Powers of Denver stated that while there were a vast number of contributions to this subject, but very few of them bore the test of rigorous analysis. The majority consisted of scattered cases of recovery from sepsis, a serum having been employed. Scientific details were lacking. He said that in his analysis he would be guided by the following principles: (1) Isolated reports of one or a few cases would be omitted. Most reports of this character emanated from physicians who, being perhaps unfamiliar with surgical diagnosis and operative management, chose the use of a serum when medical measures failed, and did not give their patients the benefit of ordinary surgical procedures. (2) As far as possible, dependence would be made on the testimony of surgeons, embodied in systematic writings on infections, where, under the head of treatment, serotherapy was compared with other measures and a verdict thereby rendered. (3) Scientific requirements should be fulfilled as far as possible. It should be shown in individual cases that a correct diagnosis had been made, and that the infection was a pure one. Further, the mere fact that a patient recovered was not sufficient for a demonstration. Further, given the special symptoms produced by a certain germ, it should be shown that the serum shortly after its administration favorably modified these symptoms so far as the latter could have been due directly to the specific toxemia or bacteriotoxemia of the disease. But few articles reached this standard, and analysis of these showed that at present serotherapy was valueless in sepsis other than that due to tetanus. Antistreptococcic serum had failed to gain a place in surgery. This sustained Vaughan's contention of two years ago. The serotherapy of tetanus had a place, but its exact value was as yet unknown. It seemed probable that while it failed to cure severe and advanced cases, it had effect in early and mild cases. As a prophylactic measure, it seemed to have achieved a standing, yet many fatal cases developed despite its early use. Further, it was never possible without bacteriological proof to say that tetanus would have developed in the cases in which it was used.

Bacteriological Studies in the Surgical Clinic.—Dr. Willis G. Macdonald of Albany, N. Y., spoke, first, of the necessity of constant cultural work, in order that the personnel of the clinic might be made alert and to feel a personal responsibility. Second, to establish consistent daily detail work, both in the wards and in the operating room, without constant criticism. Third, to be able to trace to its source occasional infection and remedy it before serious damage was done. Fourth, to establish the inefficiency of many plans recommended in medical literature which were essentially fallacious, as, for example, the fourfold gauze mask. There remained another and equally important function of surgical bacteriology, namely, its purely clinical and diagnostic value in tuberculosis, tetanus, actinomycosis, and other infectious processes.

Traumatic, Gastric and Duodenal Ulcer, Due to a Direct Blow, Revealed by Operation.—Dr. A. F. Jonas of Omaha said the progress of cases of extensive contusions that occurred after severe blows to the stomach and intestines was rapid; death occurred early, unless prompt surgical aid was brought to bear. It was difficult to judge correctly in cases in which the injury had produced a contusion or laceration of a part of the gastric parietes, as, for instance, the mucosa, or where a hematoma had developed between the coats of the gastric wall, *i.e.* between the mucosa and muscularis.

The Treatment of Gastric and Duodenal Ulcers and Benign Obstructions of the Pylorus.—Dr. Archibald MacLaren of St. Paul, Minn., said the question how we might distinguish between medical and surgical gastric ulcer was of the greatest importance to the medical world to-day. It was known that some ulcers cured themselves, and that many gave no symptoms. Shattuck said: "There are only two conditions occurring in gastric ulcer which demand operation: (1) Perforation; (2) obstruction." He agreed with him in the necessity of operating in these two classes. In perforation due to an acute ulcer, if the opening could be closed, the wound sponged or irrigated, a large-sized suprapubic drain put in soon after operation, a large percentage would recover, with the aid of Fowler's position. In obstruction cases the condition was mechanical, and demanded mechanical relief. One other class should be added to this list, *i.e.* relapsing gastric ulcer; the ordinary medical treatment was useless in these cases; proper medical treatment was putting the patient to bed, taking away all food by mouth for some days, supplying water and nourishment by rectum. He reported two cases lately seen of congenital obstruction, one dying after gastroenterostomy, the other without operation. Gastroenterostomy was the most popular; the posterior no-loop operation, last described by Mayo, was the best operation. The anterior long-loop operation was followed by a relapse, due to dragging of the loop on the anterior suture line, producing contraction of the opening. Now that the anterior operation had given place to the posterior no-loop operation, we did not hear so frequently of the necessity of closing the pylorus.

Early Operations for Cerebral Hemorrhages of Childhood.—Dr. Charles H. Frazier of Philadelphia said that in order to put on a rational basis the surgical treatment of epilepsy, greater discrimination must be made in the selection of cases. No opportunity should be lost in operations upon epileptic subjects to observe as closely as possible the existing pathological conditions. A more intimate knowledge of the pathology of the disease was necessary for the establishment of a basis upon which to determine the propriety of operative intervention and the character of the same. Epilepsy developed sooner or later in from 30

to 50 per cent. of cases of infantile hemiplegia. In many of these the lesion had been proven by autopsies to have been a hemorrhage, and in children the hemorrhage was often either on or near the cortex, rather than intracerebral, as in adults. The tendency toward secondary degenerative changes, such as atrophy, and softening, the greater disposition in epileptic subjects toward mental defects, especially idiocy, and the otherwise hopeless nature of the disease, constituted the principal arguments for surgical intervention.

Intussusception.—Dr. Ellsworth Eliot of New York contributed a paper on acute intussusception in infants and young children, in which he reported seven cases, with four recoveries, and three deaths.

Pulsating Exophthalmos; Ligature of Common Carotid, External Carotid, and Superior Thyroid Arteries.—Dr. Joseph Ransohoff of Cincinnati presented a case of this nature. The patient was twenty-one years of age, and after an injury to the temple had paralysis of the outer rectus and a pulsating exophthalmos. The pulsating exophthalmos did not come on until about four weeks after the injury was sustained. It was not known how long the paralysis of the abducens had continued. There was intense chemosis of the ocular conjunctiva, which threatened to produce ulceration of the cornea. There was no pain, but great distress produced by the ringing and buzzing noises in the head. The case was treated by tying the common carotid, external carotid, and superior thyroid arteries. This extensive operation was done through one incision and was made in order to prevent as far as possible the establishment of an anastomotic circulation too early. Three months after the operation the patient continued well, without return of pulse in the facial or temporal artery. The abducens paralysis persisted. The author had collected twenty-one recent cases in which the tying of the common carotid artery resulted in fourteen cases.

Medico-Military Notes in Manchuria.— Colonel John Van R. Hoff, U. S. Army, said that the remarkable sanitary results achieved by the belligerents in Manchuria had taught the world: (1) That there was no legitimate reason why in war the mortality from disease should exceed that from trauma. (2) That the extraordinarily large excess of deaths from battle injuries over those from disease, obtained for the first time in history, was directly due to the observance of well-established hygienic rules, proper sanitary organization, sufficient personnel, and adequate material, not to mention persistent fighting. (3) That so far as known to the writer, this war had developed nothing new in medical treatment or surgical technique; its one lesson for us was summed up in a single word, *prevention*. The Russian hospital records in the Far East to September 1, 1905, not including Port Arthur, account for 352,412 cases, of which 8,983 died in the theater of war, 24,255 were discharged for disability, 120,394 recovered, and 25,135 remained under treatment. The deaths from disease, at home and abroad, totaled 18,830, from wounds in hospital 3,541, killed on the field 19,467, missing 39,729. A very large proportion of, if not all, the "missing" probably died on the battlefield, and if so counted would give 3.3 killed to 1 dead of disease.

Cerrebellar Hemorrhage.—Mr. Hamilton A. Ballance of Norwich, England, reported a case of traumatic hemorrhage into the left lateral lobe of the cerebellum, treated by operation and followed by recovery of the patient.

Officers.—The following officers were elected: *President,* Dr. Dudley P. Allen of Cleveland, Ohio; *Vice-Presidents,* Drs. Thomas W. Huntington of San Francisco, Cal., and A. F. Jonas of Omaha, Neb.; *Secretary,* Dr. Robert G. Le Conte of Philadelphia, Pa.; *Recorder,* Dr. Richard H. Harte of Philadelphia; *Treasurer,* Dr. Chas. A. Powers of Denver, Col.

Place of next meeting, Washington, D. C., in conjunction with the Congress of Physicians and Surgeons, 1907.

Medical Items.

Treatment of Infantile Umbilical Hernia.—Steinhel refers to several leading authorities who do not believe in the radical cure for infantile umbilical hernia. Segond advances as an argument against operation in these cases the fact that in pigs and cattle, which are commonly subject to umbilical hernia, recovery is the rule. The writer then refers to various methods which have been employed in the treatment of this affection. Compression is applied in various ways. Some physicians use a layer of collodion over the tumor. Others employ a convex object for retaining the hernia in place. Again a tampon of cotton wool is used by others. The writer has collected thirty-five observations of radical cure of infantile hernia from the reports of Broca. The permanent results are known in a number of these cases; in twenty-two of them there has been no recurrence for a varying number of years. As a rule the scar is almost imperceptible. Rogier had nineteen recoveries and three recurrences in the case of twenty-two children. Estor had nineteen recoveries and one recurrence in twenty cases.—*Journal de Médecine de Paris.*

Wounds of the Heart and Great Vessels.—Biondi records nineteen cases of wounds of the heart and great vessels observed by him. In wounds of the cavity of the right heart or pulmonary artery death is not so sudden that voluntary acts may not precede it. In wounds of the left heart death is so sudden that the wounded man falls unconscious where he stands from rapid hemorrhage. The same is the case in wounds of the aorta. In hemopericardium death is more or less rapid, according to the size of the wound, and in most cases the patient remains conscious. Wound of an important branch of the coronary artery contributes to the lowering of arterial pressure. Lesions of the nerves and ganglia of the heart seems to have no great weight in determining the symptomatology of these wounds, the main factor being severe hemorrhage. —*La Riforma Medica,* May 12, 1906.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending August 10, 1906:

SMALLPOX—UNITED STATES.

		CASES	DEATHS.
Florida, Duval County	July 28–Aug. 4	1	..
Escambia County	July 28–Aug. 4	1	..
Illinois, Galesburg	July 21–28	3	..

FUNCTIONAL DERANGEMENT OF THE EARS AND UPPER AIR TRACT IN THE INSANE.*

By W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

The following observations were undertaken for the purpose of showing the relation, if any there might be, between insanity and functional derangement of the ear and upper air tract. In order to err on the conservative side, when there was doubt in the results of an observation, it was classified as normal, thus giving the weakest possible showing for the relationship of ear disease, tinnitus, and hallucinations of hearing.

One hundred and sixty-one patients were examined at the Manhattan Hospital. Most of these cases were chosen on account of their hallucinations of hearing. The rest were taken by accident, without any special plan. The observations that could not be made accurately have been classified as normal. The psychiatric classification is as follows: Dementia præcox 63, paranoia 20, dementia paralytica 20, alcoholic insanity 19, mania depressens 16, senile dementia 14, epileptic insanity 6, various 3.

The ear classification is as follows: Otitis media catarrhalis 71, otitis media purulenta (active or cicatrized) 38, foreign bodies 14, labyrinthine or nerve disease 23. In 10 of these the diagnosis was definitely established; in 13 the diagnosis was not positively differentiated from adhesive processes in the middle ear. Among the 161 cases there were 15 with no ear disease.

Hallucinations of hearing, 134 cases.
- With ear disease, 120.
- No ear disease, 14.
  - With neither tinnitus nor ear disease, 9.
  - With tinnitus and no ear disease, 5.
- With tinnitus, 63.
- No tinnitus, 71.

No hallucinations of hearing, 27 cases.
- With ear disease, 25.
- No ear disease, 2.

Ear disease, 146 cases.

No ear disease, 15 cases.

A
- With tinnitus, 6.
  - With hallucinations of hearing, 5.
  - No hallucinations of hearing, 1.
- No tinnitus, 9.
  - With hallucinations of hearing, 8.
  - No hallucinations of hearing, 1.

B
- Hallucinations of hearing, 13.
  - Tinnitus, 5.
  - No tinnitus, 8.
- No hallucinations of hearing, 2.

*Read before the New York Neurological Society, May 6, 1906.

Tinnitus, 74 cases.
- With hallucinations, 63, 85 3-10 per cent.
- No hallucinations, 11.
  - (General paresis, 5.
  - Epileptic mania, 1.
  - Dementia præcox, 4.
  - Exhaustive psychosis, 1.)

No tinnitus, 87 cases.
- With hallucinations, 71.
- No hallucinations, 16.

(If the cases where hallucinations of hearing were not definitely established are classified with no hallucinations, the proportion is 51 to 36; 58 6-10 per cent.)

Only 3 cases out of 161 had perfectly normal hearing.

The nasopharyngeal conditions were as follows: Total or partial obstruction of the passage, 79; obstruction above lower turbinate, 15; hypertrophic conditions without obstruction, 37; atrophic conditions, 5; normal, 25. As might have been expected, the nasopharyngeal conditions were as bad as the aural conditions.

Our figures show that there were 134 cases with hallucinations of hearing, of which 120 had ear disease; that is, 89½ per cent. Among the 134 hallucination cases, there were 63 cases which had tinnitus, or 47 per cent. Of the total 161 cases, 74 had tinnitus, and of these latter, 63, or 85 3-10 per cent., had hallucinations of hearing. Of the total 87 cases without tinnitus, 51 had established hallucinations of hearing, or 58 6-10 per cent.

Case I.—Admitted May 2, 1905; a laborer, age eighteen, with no education; family history negative; diagnosis, dementia præcox; prognosis, poor. For five months previous to admission he had acted strangely and had refused to go out of the house. He said people stared at him. He slept poorly, and at times refused to speak. Upon admission he was depressed and morose, and exhibited mental deterioration. He had delusions of persecution and hallucinations of hearing. He had had no previous attack of insanity.

Examination May 3, 1905, showed otitis media catarrhalis chronica; hearing for right ear, 36/72; for left ear, 42/72. Mucopurulent secretions were abundant in the nasopharynx. The nose showed some atrophic rhinitis and purulent crusts on the right middle turbinate. The septum deviated to the left and there were a spur and synechia, and partial occlusion of the left side. He had ringing noises, mostly in the left ear. There was vertigo all the time, with tendency to fall forward, and frontal headache. The otorhinological prognosis was good.

The drainage of the left ethmoid, maxillary, and frontal sinuses was promoted by the intranasal removal of sufficient tissue. On the left, the passage was cut out to allow for free respiration and prevention of contact. The headaches ceased and the purulent discharge stopped. He became comparatively bright and interested in his affairs. The tinnitus has continued to a slight degree. February 7,

1906, the watch was heard by the right ear, 60/72; in left ear, 76/72.

March 17, 1906, there were no hallucinations of hearing. He still had ringing tinnitus in the right ear. There was no headache and no pus in the nose. He was paroled and a month later discharged.

Case II.—Admitted April 29, 1905; a tailor, fifty-six years old; intemperate; family history negative; diagnosis, terminal dementia; prognosis, unfavorable. He was depressed, quiet, and talked little English. He had insomnia, talked to himself, and had auditory hallucinations in his right ear. He made mistakes in the identity of persons. Orientation as to time appeared correct, but was poor for places. He had no insight. His physical condition was good.

Examination, May 3, 1905, there was slight chronic middle-ear catarrh. The hearing was very much reduced, in fact, nearly lost. No sound was heard by bone conduction. There were mucopurulent secretions in the nasopharynx. The occlusion of the left nostril, due to spur and enlarged turbinate, was complete. He had whistling tinnitus in his right ear and heard voices at night in the right ear.

May 17, 1905, the nose was free, the hearing much improved; for right ear, 1/144; for left ear, 3/72. He still had a little discomfort in the right ear. He had no tinnitus, nor hallucinations of hearing.

Case III.—Mania depressens. The patient was a young married woman who did not expect to survive her confinement. A few days after the confinement, an acute purulent inflammation of one middle ear developed, with severe mastoid symptoms. Her mind completely gave way with the dominant idea that she was to die and that there was nothing to live for. As the aural condition improved, her mental state gradually grew better.

Case IV.—Admitted May 2, 1905; a tailor, fifty-four fears old; diagnosis, paranoia; prognosis, bad. His mother, father, uncle, and two sisters were insane. He had not been right for twelve years previous to admission. He had attacks of depression and was unable to hold his position; he was confused, nervous, and slept poorly. Upon admission he was depressed and much worried. He had delusion of persecution and hallucinations of hearing.

May 3, examination showed otitis media catarrhalis chronica, which had been treated; hearing for watch, right ear, 9/72; left ear, 15/72; hearing by bone conduction much reduced. The nose was completely occluded by the enlargement of all four turbinates. He had "sizzing" tinnitus in both ears. It was worse at night and during a "cold." He was dizzy, nearly falling forward; had headaches and was confused. He was very hypochondriacal and imaginative. He heard voices in his head. There were no visual hallucinations. The otorhinological prognosis was good, the psychical prognosis poor. Later on, portions of the turbinates were removed until there was free breathing space and no intranasal contact. Strychinine, potassium iodide, and thyroid gland were given at different times. He was paroled April 10, 1906, with general and mental condition improved very much. His otic condition remained the same.

Case V.—Admitted July 6, 1905; twenty-four years old; excessive indulgence in alcohol; family history negative; diagnosis, dementia præcox; prognosis, poor. The patient showed an indifferent, inconsistent, and irrational reaction. He was subject to telepathic influences. There was orientation and partial insight. He had hallucinations both of hearing and sight. He had had no previous attack. On August 2, 1905, five large diptera larvæ had been removed from the left ear. The ear showed otitis media purulenta healed. The hallucinations of hearing were relieved.

Case VI.—Admitted January 2, 1906; an artist, thirty-nine years old; family history negative; diagnosis, general paresis. He had been admitted three times previously and discharged, improved. For the past month he had been quite restless and thought the hospital circulated stories about him. He also thought that his people were trying to poison him He refused to eat or sleep. He had no hallucinations. The hearing for the right ear was 4/72; for the left ear, 1/72. There were signs of middle ear involvement, as well as nerve deafness.

Case VII.—Admitted April 17, 1905; a boy, sixteen years old; family history negative; diagnosis, dementia præcox. Three weeks previous to admission he refused to speak and would sit quietly in a corner and laugh to himself. At times he became noisy and imagined that he was Christ and could talk to God, etc. Previous to this time he had had buzzing in both ears. He now had hallucinations of hearing and sight. June 16, 1905, hearing good, no tinnitus nor hallucinations; adenoids; no vertigo; occasional headache.

Case VIII.—Patient a female; domestic; married; infectious exhaustive psychosis; father insane; prognosis good; gave birth to a child three and one-half months ago. Since then she has had peculiar ideas, has been disinterested in everything, and imagined that she was to be killed. She drank ink and ate pins in order to die. The suicidal tendencies deepened. There was internal strabismus, with nystagmus. There were no hallucinations of hearing. There had been no previous attack of insanity. The present attack began six months ago. Both membrana tympani were much retracted. There was catarrh of the Eustachian tube. The mucosa of the upper air tract was dark-bluish. The middle turbinate was hypertrophied. There was lateral pharyngitis, with occasional tinnitus by day or night.

Case IX.—Admitted November 9, 1895; a man, thirty years old; cigarmaker; single; family history negative; prognosis unfavorable. He had no friends and no information concerning him could be obtained. He was silly and foolish in demeanor, with attacks of violence. He exhibited much mental deterioration; he was confused, and refused to speak. He took snuff. He had no hallucinations. There had been no previous attack. Examination, March 14, 1906; hypertrophied turbinates; otitis media catarrhalis chronica; watch heard in right ear, 30/72; left ear, 36/72. There was no tinnitus, vertigo, nor headache. There were no auditory hallucinations.

Case X.—A leather worker, twenty years old; family history, a sister who was peculiar; diagnosis, dementia præcox. For two years the patient had acted queerly; had been depressed, apathetic, and indifferent; laughed without cause; thought he had a disease of the stomach from eating food which had been cooked in unclean, rusty dishes. He had stigmata. The reflexes were exaggerated. No hallucinations were established. Seen July 26, 1905. Otitis media catarrhalis chronica; watch for right ear, 36/72; left ear, 30/72. There was granular pharyngitis. The lower turbinates were much enlarged. He sometimes had ringing tinnitus. There was no vertigo nor headache. He was discharged improved, September 30, 1905.

Aural disease seems to have, in some cases, an effect on the form of the psychosis by giving rise to hallucinations of hearing through the suggestions given by subjective sounds or tinnitus which are exaggerated by deafness (see table of cases). In a smaller number of cases, ear disease appears to be

an exciting cause of insanity because of its influence on psychic functions through its multitude of subjective symptoms as well as systemic infection. (Case No. 3.) Certain nasal disturbances seem to have some psychical effect through the not uncommon symptom of intranasal pressure; *i.e.* fullness of the head and aporexia. (Cases 1 and 4.)

Nasopharyngeal and aural diseases in their relation to insanity may be classified under five heads: 1. Nasopharyngeal and aural disease which has no relation to the coexistent psychical disturbances. (Case No. 9.) 2. Nasopharyngeal and aural disease consequent to insanity. (Case No. 8.) 3. a means of diagnosis, not infallible of course, yet Nasopharyngeal and aural disease due to the same cause as the coexistent insanity. (Some alcoholic and dementia paralytica cases, No. 6.) 4. Nasopharyngeal and aural disease a determining factor in the symptoms of the psychosis. (Cases Nos. 1, 2, 4, 5, and 7.) 5. Nasopharyngeal and aural disease the exciting cause of the insanity. (Case No. 3.)

Some of the cases of dementia præcox seen suggest that they may be influenced by nasopharyngeal disease alone, which causes aprosectic symptoms, with or without ear disease and hallucinations of hearing. (Case No. 1.) Or there may be ear disease causing hallucinations of hearing independent of nasopharyngeal disease. (Case No. 5.)

The number of cases we have observed is not large enough to prove any point conclusively, but they suggest what might have been expected, *a priori*, namely, that nasopharyngeal or aural diseases are much more prevalent among the insane than among normal individuals, and that sometimes hallucinations of hearing appear to be excited by subjective sensations of hearing, and that aprosectic psychosis is sometimes aggravated, if not excited, by intranasal pressure. They also suggest the possibility of improving a small number of cases by care and correction of their nasopharyngeal and aural defects.

The prognosis for psychical improvement from treatment of the nasopharynx in the cases where nasal complication is a disturbing factor, is good. (Cases No. 1, 2, 4, 7, and 8.) The prognosis is also good when active aural disease is a disturbing factor. (Cases 3 and 5.) The prognosis is bad where chronic inactive aural conditions are a disturbing factor. These cases are difficult to treat even with the cooperation of the patient. Without this cooperation they are still more difficult. Perhaps after more experience, some practical way will be developed for the care of similar cases.

The improvement among the 161 cases due to otorhinological treatment was only 3 7-10 per cent. Out of the selected cases, however, about 62 per cent. showed marked improvement, and the balance (38 per cent.) showed some improvement.

For bibliography and a few additional cases of successful aural treatment of auditory hallucinations on catarrhal middle ear inflammation, see my article, "Tinnitus Aurium and Hallucinations of Hearing," *Annals of Otology, Rhinology, and Laryngology*, St. Louis, September, 1905.

57 West Fifty-third Street.

An Unusual Indication for Cesarean Section.—Brunet had recourse to this operation in a case of severe hemorrhage from unusually large varicosities of the vagina. The bleeding could be controlled only by packing, and each time that the dressing was changed the hemorrhage endangered the patient's life. It therefore seemed inadvisable to permit delivery by the normal route, and cesarean section was followed by recovery of the mother and the delivery of a healthy child.—*Centralblatt für Gynäkologie.*

THE THERAPEUTIC VALUE OF ARTIFICIAL LOCALIZED HYPEREMIA IN THE TREATMENT OF AMBULATORY OR DISPENSARY CASES.

WITH A REVIEW OF THE PUBLISHED RESULTS AND A REPORT OF PERSONAL OBSERVATIONS.

By EDWIN BEER, M.D.,

NEW YORK

ATTENDING SURGEON TO SYDENHAM HOSPITAL; CHIEF OF CLINIC IN SURGERY TO BELLEVUE HOSPITAL AND MONTEFIORE HOME

Since the startling publications of Bier and Klapp on the use of hyperemia in acute inflammatory conditions, in 1905, German medical literature has been flooded with papers on this subject. In other countries very little notice seems to have been taken of these most valuable and important contributions. It is with the hope of stimulating interest in this new and productive field that I have brought together in this paper the following data, based on the experience of myself and others. The bibliography that is appended will show at a glance the recent development of this branch of therapeutics, as well as the preponderant, if not exclusive, activity of Germans in this line of work. Moreover, a glance at the different titles of the published papers will give an idea of the wide use that already is being made of this therapeutic agent.

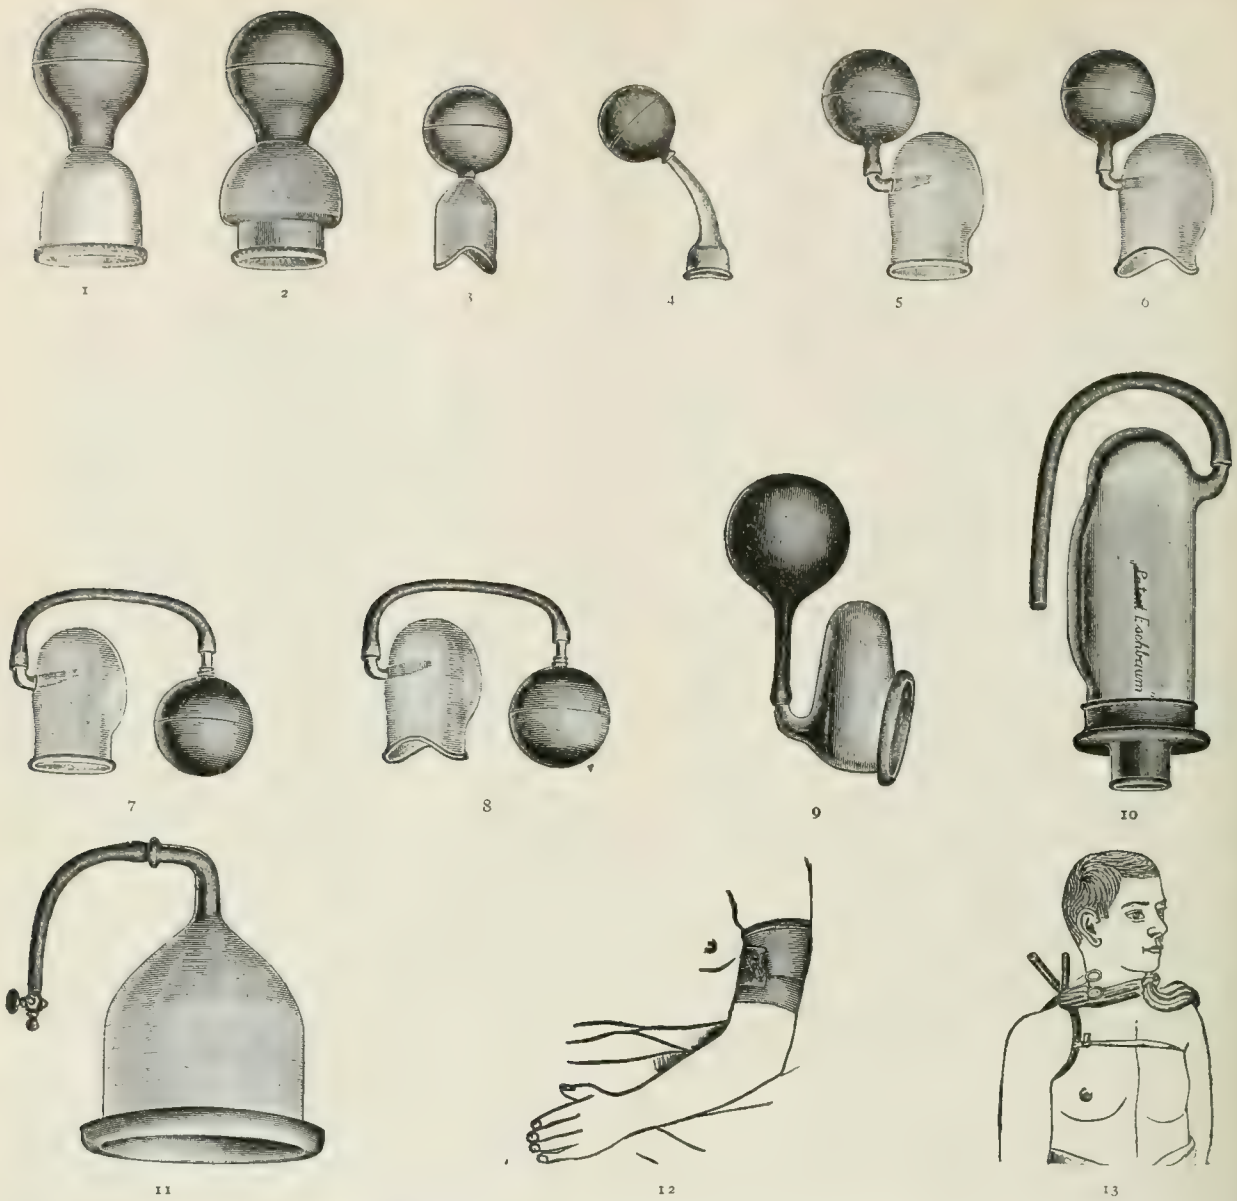
After careful and analytical study of inflammatory diseases Bier came to the conclusion that hyperemia is Nature's most efficient weapon in combating disease; that the antiphlogistic method of treatment, now so generally employed, interferes with Nature's efforts and is radically wrong. Starting from this premise, he saw that to assist Nature her processes must be imitated. In the attempts at imitating these a whole new system of treating inflammatory conditions has been developed by Bier, and the many successes of this new system are destined to raise it to an enviable position in the list of therapeutic agents. It scores victories where older methods fail. It often succeeds quickly and painlessly where older methods are slow and painful. It frequently leads to cures bloodlessly, while the older technique demands operative interference.

Believing as I do, that artificial localized hyperemia is a most important therapeutic agent, and that as years roll on it will be used more and more extensively, this review of published cases and of my own results needs no excuse.

The subject-matter of this article will be subdivided for sake of clearness. First, I shall describe the various methods of producing artificial localized hyperemia and the application of these methods in various diseases. Finally, I shall attempt to give some explanation of the workings of hyperemia in these conditions. The bibliography is appended for those who wish to acquaint themselves more intimately with the literature.

Most of the methods employed to induce a localized hyperemia are as old as the hills, and have, in fact, been used, without being properly understood, for ages in producing local or systemic effects. Bier has the credit of systematizing and of elaborating these older usages. In addition, he has explained practices which have been passed from generation to generation, so that what was purely empirical has now some scientific foundation.

There are two kinds of hyperemia, active or arterial, and passive or congestive or venous. The former Bier produces by the use of heated air. This type of hyperemia has been particularly useful in chronic rheumatic joints, and is well recognized as



1 2 3 4 5 6 7 8 9 10 11 12 13

* Various forms of apparatus for inducing localized hyperemia; 1-11, for suction hyperemia; 12 and 13, for constriction hyperemia.

an efficient agent. In the 150 odd cases, which underlie this report, I have not used this method at all, as it was not practicable in my services. The two methods employed by me may be named (1) *Hyperemia induced by Suction* (*Saug-Hyperemie*), and (2) *Hyperemia induced by Constriction* (*Stauungs-Hyperemie*).

In the former, for short called suction hyperemia, a mixed hyperemia is induced, though the venous element probably preponderates very early in the treatment. This form of hyperemia is produced by cupping the part to be treated. As Bier tells us, this method is as old as the human race, as cups of one sort or another have been used by the most primitive people; in fact, it seems to me coeval with the birth of the higher animals, for all animals induce this type of hyperemia, when they suck their wounds, which action so regularly prevents the infection from becoming a progressive one. Recently I had an opportunity to see this primitive form of suction used by a baby in combating a paronychia with beneficent effect.

The instruments required to induce this form of hyperemia are very simple, consisting of a glass vessel and some means of rarefying the air within the same. Bier has had a large assortment of cups made, which are particularly useful, being of different sizes and shapes, so as to adjust themselves readily to all surfaces of the body. Cups made after the designs of Bier and Klapp will be found in the American market before long.

I have reproduced in the illustrations the more essential types of the apparatus required to produce suction hyperemia, and as the pictures explain themselves I shall not describe them *in extenso*.

Figures 1 to 4 are simple cups made in various sizes and shapes to fit over flat and curved surfaces of the body. Suction is produced by compression of the attached rubber ball. These are the simplest of all appliances, and are, to all intents and purposes, nothing but dry cups. They are open to the objection that they cannot be kept sterile, as the pus and blood drawn out of treated abscesses, etc., will contaminate the interior of the ball, which in turn will not stand boiling for any length of time. Personally, I have employed this type of appliance more than any other, as it is cheaper, more readily obtainable, and just as effective as the other models.

The more elaborate appliances are pictured in Figures 5 to 8. They are so constructed that pus, etc., cannot run into the ball. The glass cup is separable from the ball and can be boiled. Figure 9

represents another type of cup, in which the glass reservoir is irregularly shaped, so as to allow of the collection of all pus and blood in the glass reservoir and prevent its entrance into the rubber ball. In Figure 2 a similar function is performed by the bulging of the glass cup a short distance from its rim. Figures 10 and 11 represent cups that are used in specific regions. These are made of ample size, and, instead of a ball pump, an aspirator of greater power is used. Figure 10 represents the cup used for fingers and Figure 11 represents that used for the female breast or large inflammatory areas. In addition to these simpler, and, on the whole, smaller instruments, Bier has very large suction apparatuses, which are so made as to surround large parts of the extremities, *e.g.* the whole hand, or arm, or knee joint, and the like. These I have not had occasion to use as yet. They are fully described in the second edition of Bier's book on hyperemia.

No matter which cup is used, one must avoid infecting one patient from the other. Apparently this does not seem a likely event, as in the many hundred applications I have made I have never encountered such an accident. Still that must be guarded against, and the only way to do so is by sterilizing the cups after use. If one uses the detachable apparatus the glass should be boiled; if one uses the nondetachable, old-fashioned cups, antiseptic solutions, friction, and occasional boiling must suffice.

In applying these cups to an inflamed part the two cardinal rules that must be adhered to are: (1) The procedure should not cause pain; (2) the suction should be intermittent. Both rules are easily followed. Excessive suction causes pain, consequently one must employ a lesser degree, the patient indicating by his sensations when the amount of suction is excessive. After a few trials that difficulty is overcome. Equally important is the second rule. The suction must be intermittent, otherwise it is of very little use. The cup is applied with or without greasing the rim and moderate (painless) suction is induced. The cup remains in place three or four minutes and is then removed for one or two minutes. After this it is reapplied, as at first, and after three or four minutes it is again removed for one or two minutes.

This process is repeated for from thirty to forty minutes. This may be called one treatment. In dispensary work one is able to give such a treatment daily, or every other day at most, depending on the arrangement of one's service; but in private work I have given two or three such treatments a day, as I have convinced myself that the more frequent use of the cups is decidedly beneficial. If this method is employed in the treatment of an abscess, a small incision is made in the center of the focus. Then a cup, of approximately the size of the area of inflammatory reaction, is selected and applied, painlessly and intermittently. After the suction is used for some time the patient frequently states that the pain inherent in the inflammatory focus is diminished or gone. As the suction continues blood and pus are drawn from the abscess cavity into the cup and the abscess is emptied. After the close of such a treatment the swelling of the parts is much greater than before, and the abscess cavity is overfilled with a blood clot which projects into the incision; the cavity thus filled with healthy clot requires no drain. It is evident that the suction produces a local edema about the focus, while it also produces a hyperemia of the granulations in the wall of the abscess cavity whence is derived the clot that fills the abscess cavity when the treatment is terminated.

This whole process naturally effects an early separation of dead from living tissues, with discharge of all pus and sloughs. At times such therapy succeeds in dispelling the focus even without incision of the abscess. In such cases the pus gives way to serum, as can be verified by the aspirating needle, and this in turn is also absorbed.

I shall illustrate the method and result of this treatment in the following cases, so that all those who wish to try it may have full details as to the simple technique:

Case I.—W. G. Diagnosis: Furuncles of neck and arm.

June 26: Tender inflammatory mass one and one-half inch in diameter on back of neck. Over center of this indurated area is a small opening (spontaneous) discharging pus. Cup applied intermittently and painlessly for (lack of time) fifteen or twenty minutes. Pus and blood drawn out of the cavity, marked swelling of tissues that have been cupped. Wet dressing applied. No drain.

June 28: After last treatment all pain disappeared. Great improvement in local condition. Practically no discharge. Signs of inflammation almost entirely gone. Suction hyperemia again as above for fifteen minutes. Wet dressing.

June 30: All signs of inflammation gone. Opening closed. Patient cured. Patient developed a larger abscess on his arm, which was first opened by a very small incision, and then treated as the abscess on his neck. This received fifteen minutes' suction hyperemia applied as above, then wet dressing and no drain. On next visit,

July 3: Almost all signs of inflammation on arm gone; incision is closed. Suction hyperemia for ten minutes.

July 5: Discharged cured.

Epicrisis: In this case two abscesses were treated painlessly and successfully. One was completely cured in four days without incision. The other in five days with a minute incision. No painful insertion of drains was resorted to, and the procedure itself acted as an analgesic.

Case II.—H. P. Diagnosis: Abscess of neck.

August 1, 1905: Patient has had tender, painful swelling on back of neck for past three or four weeks. About two and one-half weeks ago it began to discharge pus. At time of first treatment patient had an abscess about one and one-half inch in diameter just below hair margin on back of neck. It was discharging pus from a small opening. Whole area about abscess was tender, red, and swollen. Abscess fluctuating. After enlarging the opening to one-half inch suction hyperemia applied for twenty or twenty-five minutes. About one ounce of pus evacuated. Wet dressing.

August 3: Patient returned. Absolutely no local signs of inflammation, no pus; wound practically closed. Discharged.

These two cases are sufficient to illustrate both the methods and results of treatment of abscesses by means of suction hyperemia, and so far as the technique is concerned, I trust I have made that perfectly clear. It is not necessary to describe in detail all the cases that I have treated by this method, and to avoid discursiveness I have classified the ninety odd cases treated by artificial hyperemia induced by suction, so as to show at a glance in what diseases or conditions it is useful.

1. *Prophylaxis against infection*—eight cases. In the literature of our subject I find no mention of the use of suction hyperemia to prevent infection in incised and perforating wounds of the extremities. Its use in such cases is, perhaps, too self-evident to deserve much comment. I have found it particularly

efficacious in these cases, as it cleanses the wound, and, so to speak, produces a local immunization and a reaction before the infection has a chance to become active. Here we imitate the time-worn custom of sucking out wounds, but do it in an aseptic and cleanly manner. I have been almost invariably successful in this application of hyperemia. In just these cases the older therapy would counsel wet dressings and would fail to combat the incipient trouble, except in so far as the hyperemia induced by the wet dressings might prove effective. In this connection I must call attention to the fact that hyperemia will, in my opinion, prove a great blessing to the surgeon who injures his fingers during a septic operation. From what I have seen in my cases I feel sure that early use of this form of hyperemia will save many a surgeon weeks of pain and inactivity.

2. *Infected wounds and cellulitis of fingers or of hand*—twenty-six cases. In these conditions suction hyperemia works remarkably well. At times it succeeds in dispelling acute inflammatory foci without incision. Instead of cutting into the swollen and tender painful part and looking for a few drops of pus, one frequently succeeds in the early stages by using hyperemia in causing an absorption. In the latter stages a small incision followed by suction leads to rapid relief of all subjective symptoms, and to rapid subsidence of the inflammation without all the painful trials incident to the older method, of liberal incision and packing with gauze drains.

3. *Abscesses, furuncles, carbuncles**—thirty-five cases. Here we need not delay long, as in the cases cited *in extenso* above I believe I have clearly shown how effectively and how painlessly suction hyperemia leads to a rapid cure of the condition. There is, however, one type of abscess which has always given the surgeon concern; I refer to mammary abscess; and this deserves special notice. It is to the credit of Klapp to have shown that with the use of suction hyperemia the old mutilating radial incision of the breast may be dispensed with without any danger to the patient. In five cases of this kind I have verified his statements. By small incisions into the inflamed areas and subsequent suction, I have regularly avoided the unsightly as well as mutilating incisions that are still so generally used in suppurative mastitis, and at the same time have almost painlessly and rapidly obtained a complete cure.

4. *Acute suppurative adenitis*—six cases. Here, again, suction hyperemia scores a decided victory. After a small incision into the gland or glands which are suppurating three or four applications of suction hyperemia will almost regularly lead to a definite cure. In one such case, however, I failed absolutely. I could not cover the whole area of inflammation with my largest cup and the process extended to adjacent glands. This case was treated subsequently by the usual open method, very little being sacrificed by the trial of suction hyperemia. This case was very instructive to me, as it showed me that I should not attempt to control the more extensive inflammatory processes with cups unless I had cups of size adequate to encompass the inflamed area. Several other cases in which there existed a marked disproportion between the extent of the inflammatory area and the size of the cup testified to the uselessness of suction hyperemia when too small a cup was employed.

5. *Acute bursitis*—seven cases. Almost all of these cases were situated over the olecranon and presented the picture of a suppurative process. In two cases I opened the bursa by a small incision and several drams of pus were evacuated. All these cases responded in a gratifying way to artificial hyperemia. The blessings of this new and simple method of treatment were markedly accentuated by the simultaneous inspection of four cases of this disease, two treated by other surgeons and referred to us for dressing, and two treated by us by the above method. The freely incised patients with their long incisions surely had the worse of the applicable therapeutic measures.

6. *Contusions (black eyes, etc.)*. Contusions with extravasation of blood do not frequently demand treatment, but when they are visible and on exposed surfaces, as about the eye, any method of treatment that offers fairly quick relief is sure to be much used. My experience in treatment of contusions about the eye is limited to two "black eyes;" but the effect of the use of suction hyperemia was so striking that I cannot forbear saying a word or two about those cases. I applied my cup over the eyeball and over both lids simultaneously. Before I had ended one hyperemia treatment the dull, blue-black color of the extravasated blood had changed to a much lighter shade and the periphery of the contused area assumed a distinct yellow color. This treatment was continued three or four times daily for a few days, and by that time the induced hyperemia had thoroughly oxidized and absorbed most of the ecchymosed blood, so that at the end of the fourth or fifth day only a few very small areas remained as evidences of the patient's original condition. In other words, suction hyperemia causes an absorption of the extravasated blood two or three times as rapidly as the usual methods of treatment, which are, to say the least, tedious and unsatisfactory.

I have also employed suction hyperemia in more chronic conditions with some success. In six cases of sinuses in soft parts and in bones I was able to obtain an unusually rapid closure of the same after using suction hyperemia. In one case I was markedly successful. After one three-fourths-hour treatment of a sinus in the head of the tibia two inches deep (no exposed bone) the whole sinus closed, so that two days later there was no opening into the bone. (This has remained closed.) In chronic ulcers, in bed sores, suction hyperemia is at times of great benefit.

Before referring to other fields of usefulness of suction hyperemia I shall cite some of the published results along the lines above outlined, and subsequently mention some of the other conditions in which it has been successfully employed by others, though as yet I have not had opportunity to test it in these conditions.

Klapp, Bier's assistant, discusses very fully the usefulness of suction hyperemia in his paper of last year. He deserves the credit of establishing this method of producing hyperemia in inflammatory conditions, though Bier had employed it years ago. These earlier attempts were given up, however, because, owing to the fact that excessive suction had been employed, they were not greeted with success. Klapp, in his attempts to produce hyperemia in parts which were not amenable to the constriction method of producing hyperemia, seized upon the abandoned method and developed an entirely novel treatment for the greatest variety of conditions.

In Bier's clinic suction hyperemia has been used with success in over six hundred cases of furuncles, carbuncles, buboes, cold abscesses, acute abscesses, mastitis, infected wounds, cellulitis, phlegmons of the floor of the mouth, insect bites, panaritia, and

*Some authors have published bad results in diabetics.

paronychia. The good results above described were regularly obtained, sometimes after a small incision had been made, sometimes without any incision.

Arnsperger, v. Brunn, Colley, Danielsen, Frommer; Fischer, Herhold, Ranzi, Volk, Necker, and Stich report results similar to those published by Klapp and identical with those obtained in my series. The total number of cases treated by the different authors aggregates considerably over a thousand, and the universal praise bestowed on this method of treating the above conditions surely goes far to prove its efficacy and to establish it permanently in the position that Bier claims for it. All agree that by means of artificial (suction) hyperemia pain is diminished, cure is hastened, large incisions are done away with, and drains are not required. Bier has laid special stress on the importance of the last point in suppuration in tendon sheaths, where the use of drains almost regularly leads to sloughing of the tendon, while in cases treated by hyperemia, whether produced by suction or by constriction, the tendons are very often saved. The presence of the drain in these cases dries the tendon and leads to its death, whereas in the new method there is no drain to do damage, and the hyperemia has a decided nutritive effect.

The suggestiveness of Bier's idea has already led to results in other branches of medicine. In eczema Colley reports cures in chronic rebellious cases. The same author publishes a case of appendicitis abscess treated by suction hyperemia with success. This case is unique, and perhaps will remain so. Sonderman, Spiess, and Muck have been satisfied with their results in aural and nasal diseases. Prym, with special cups, has used suction hyperemia in follicular, in membranous, and in chronic recurrent tonsillitis with gratifying results, obtaining rapid subjective relief. In the field of gynecology this new agent has also been employed. Rudolph, Eversmann, Kroemer, and Colley report successes. Some have treated amenorrhea successfully, others have failed. There is some unanimity concerning its efficacy in chronic endometritis, chronic metritis, and perimetritis. Special cups are required for this method, provided suction is made per vaginam. Colley claims good results by producing the suction from the hypogastrium. He declares that such suction can be felt by the vaginal finger, as it draws the floor of the pelvis toward the cup.

Up to date experience along these specialistic lines is not sufficient to establish suction hyperemia in a definite zone of usefulness. In general surgery, I believe, however, we have gathered sufficient experience to demonstrate clearly that this method of producing hyperemia is essentially practical, and such hyperemia is preeminently useful in the treatment of the conditions previously enumerated.

In addition to the method just described, hyperemia may be produced by constriction. This is the method that Bier has studied for a great many years, and which in its latest application has caused a tremendous stir in German surgical circles. In employing this method the surgeon requires, as a rule, only a thin rubber (Martin) bandage. This bandage is applied proximally to the point that is to be treated, either directly to the skin or over a few layers of an ordinary soft bandage. If a marked degree of venous congestion is desired, the bandage is applied rather firmly; if, on the other hand, only a slight congestion is desired, the bandage is applied so that it exerts but little pressure. One can best learn how to apply the bandage by employing it on one's own arm first. If the bandage is wrapped about the limb snugly to produce a marked congestion, the limb within a few minutes shows signs of venous engorgement, it feels fuller, the veins stand out, and the skin becomes bluish. The pulse in the arteries must never be obliterated. Hyperemia of this marked degree is not borne with comfort for more than one hour. If, however, one desires a much milder venous hyperemia the bandage is applied less snugly and the parts show much less venous engorgement. Now the limb becomes instead of a deep blue, a bright red, with at times the slightest tinge of blue. A patient can wear such a bandage for the greater part of a day with perfect comfort. With both methods of application the parts become edematous, due to the impaired return of venous blood and lymph. In the latter method, however, the swelling is more marked. After removal of the bandage a reactive hyperemia, arterial in character, sets in. This is most marked after the production of a high degree of venous engorgement, and is the same familiar phenomenon that is so regularly seen after the removal of a tourniquet in the production of artificial anemia for operations on limbs. These two degrees of venous congestion, produced by the use of a simple rubber bandage, must be kept absolutely separate, as the hyperemias thus produced have special and very different usages. The marked venous engorgement is particularly valuable in more chronic conditions, whereas the milder degree of hyperemia is especially useful in acute conditions. Abroad the polyclinic or dispensary services are so arranged that both methods can be employed without any danger. In my services where the control of the patients is inadequate I have been forced to employ the first method of marked engorgement almost exclusively. As the bandage is left in place at longest only one hour the patient is continually under one's eye. The second method demands that the bandage should be in place for the greater part of the day and night, shifted, if possible, every ten hours to a new position to avoid excessive localized pressure and removed for three or four hours, after twenty hours' action, and then reapplied anew. Our dispensary conditions are such as to preclude a wide use of this method, for self-evident reasons, as we lack the proper control of our cases. To employ this method we must have the patient in perfect control, as it would be dangerous to allow a case treated in this way to go out of one's sight for a day or more. In private ambulatory cases this method is very practicable as well as in hospital cases. As yet my experience with this second method is too limited in ambulatory cases to allow of a final verdict, though my results are such as to convince me that Bier's remarkable claims for the efficacy of this mild hyperemia in combating acute infections are well founded. He and his assistants, as well as others, who have better control over their material, have employed both constriction methods very extensively and very successfully. I shall refer to their results later, after enumerating the conditions in which I have employed the constriction method which produces marked venous engorgement.

In Figures 12 and 13 the method employed is illustrated. The thin Martin bandage is perfectly adequate to produce hyperemia of all parts distal to the shoulder and to the hip joints. To produce hyperemia in the shoulder joint one must use a rubber tube and apply it as in Figure 13. There is as yet no method of producing venous hyperemia in the hip joint. To produce venous hyperemia in the head and neck a narrow rubber bandage applied about the neck has proven most useful. Bier employs for this purpose a special bandage, equipped

with hooks and eyes, which I know only from his description.

I have employed marked venous engorgement in a variety of conditions, in over fifty cases which required in all hundreds of applications. Just as in the use of suction hyperemia, in constriction hyperemia I have seen no bad effects. The almost uniform and startlingly excellent results of suction hyperemia in the diseases previously enumerated were not duplicated in this series. This form of hyperemia undoubtedly acted beneficially in most cases, but in view of the fact that so many of the conditions were chronic, it was difficult to form a correct estimate of just what was effected by this treatment.

In twenty-nine cases of *stiffness of joints* following severe old contusions, or multiple healed incisions of cellulitic areas, or fractures it was difficult to gauge justly how much was done by this treatment. Pains were almost regularly relieved and motion of the part was so improved that on the whole my impression was favorable. If the patients could have availed themselves of massage, passive exercise, baths, hot-air treatment, and the like, the results might have been just as rapidly obtained. In the poorer population limbs must be made useful as soon as possible. As yet we have no method of obtaining a rapid result in this class of patients, and until the poor have the advantages, if they are really advantages, that money can buy Bier's method of hyperemia, I think, will give more satisfaction than any other method. The bandage produces a marked diminution of pain in the affected parts and the patient with bandage *in situ* can work the parts and stretch the adhesions with much less discomfort and pain. At the same time the parts become edematous and more elastic, so that they give more readily under the exercises, and often behave as if they were better lubricated. While the bandage is in place the surgeon can frequently break up adhesions, which process otherwise would be excessively painful and well-nigh impossible.

The treatment thus outlined is practically a simple method of combining passive exercises and hyperemia. Those better placed in the social scale avail themselves of the more refined methods of producing hyperemia (massage, baths, hot air, etc.), but it still remains to be proven that these methods lead to a more rapid resolution than the simpler method which I have employed in dispensary practice. A combination of both the above methods might be of great value in hastening the result that patient and surgeon desire. Blecher and Sudeck have employed constriction hyperemia for similar cases and were gratified with their results. Habs reports successful results in such cases also. Luxembourg and Tillmanns recommend this method for treatment of these conditions. All in all these authors have the same impression as I obtained from my cases, and our experiences justify Bier's claims.

In chronic rheumatic joints, in gonorrheal pains about joints, and in other vague joint conditions which present no objective features it is often astonishing how rapidly the subjective symptoms are relieved. As Bier says, there is a whole group of conditions usually following trauma which present no diagnostic features and which baffle the surgeon in which hyperemia is marvelously successful. Such cases everybody sees, and they wander from surgeon to surgeon without relief. I have seen a whole series of such indeterminable conditions and have been fortunate enough to obtain relief by constriction hyperemia without in any way arriving at a diagnosis of the patient's condition.

The efficacy of hyperemia in chronic rheumatism is well recognized, and the hot-air treatment is almost routine. The use of the bandage to obtain the same effect is recommended by some, but on the whole at present the verdict cannot be rendered as to which method is the better. In gonorrheal joints opinions are still at variance. Hirsch only recently has reported good results, but thinks them no better than obtained by other methods of treatment.

In tuberculosis of bones and joints I have been very much pleased with my results. I have employed venous hyperemia by constriction method in six cases. All cases were nonoperable. Either the patient refused to be operated upon or the pulmonary involvement was such as to contraindicate such measures. Four cases were closed and two were open with many fistulæ. Of the former one was a very old process in the knee joint with marked deformity. The patient, an old man, could not sleep because of pain. His ankylosed knee gave him a great deal of trouble and pain so that he could not get around. He was treated by Bier's method at first one hour, later two treatments of one hour daily. Finally he was taught to apply the bandage himself, and told to report from time to time. Under this treatment all his subjective symptoms disappeared and he was able to sleep through the night. He was well pleased with the result. Whether the disease has been cured I cannot say. In three other knee cases venous hyperemia produced equally gratifying relief of all subjective symptoms. In two of these the effusion in the knee joint persisted, showing that the disease had not been eradicated. In the fourth case, as in the first, the bone was alone involved and there was no joint effusion. In the two open fistulous cases the results could be watched more objectively. In one, an extensive tarsal tuberculosis, the patient was practically chair ridden with sinuses running into the tarsus from the sole of his foot. He also was taught to use his bandage twice a day, and the treatment gave him much relief. When it was begun he could not walk on his foot, and within a month he was able to walk for from twenty to thirty minutes at a fairly lively gait. The sinuses became healthy in appearance, the discharge diminished very markedly, and some of the sinuses closed completely. At this stage he disappeared from observaation. His local condition was vastly improved, though there was no reason to believe there was a cure. All these cases were treated for a few months; none remained with us the nine months' period that Bier takes to be the average length of time to produce a cure by hyperemia.

My sixth case was one of carpal tuberculosis with dozens of fistulous tracts and enormous thickening about the wrist. The patient was a very old man, and, strange to say, did not respond at all to the treatment by venous hyperemia. He has been under observation for at least eight months, and has been treated carefully and systematically by us. In this case I noticed that after removal of the bandage no reactive arterial hyperemia developed. I wondered whether this, which evidently was due to his marked arterial disease, poor heart action, and old age weakness would explain the absolute inefficacy of Bier's treatment. Pains were still present in the wrist, and locally there was practically no objective improvement after seven weeks' treatment. To test my supposition I produced an artificial anemia by bandaging the whole arm from the finger tips to the elbow without exerting undue pressure at the focus of disease. This was removed after fifteen minutes,

and, to my surprise, a fair arterial reaction developed. This procedure was then carried on for several months, and during this time I noted a well-marked improvement. Many sinuses closed, and the rest assumed for the first time a healthy appearance, the thickening became less, the discharge diminished markedly, motion increased, and pain disappeared. After giving this a good test I went back to the first method, venous hyperemia, and again found it of no avail; the progress that had been made was gradually lost again in part. Finding no response to the usual method of treating these conditions, I again took up the method above described and recovered the ground we had lost. He is still under treatment, is not by any means cured, but there is no doubt of his very marked improvement.

This case I have gone into rather fully, as it goes to show that the arterial reaction after the removal of the rubber bandage is probably very useful in the treatment of tuberculosis of bones and joints. Here the simple venous engorgement had practically no effect, whereas the arterial hyperemia had a distinct effect. More cases bearing on this point must be studied before we can attempt to explain this peculiar and unique result.

Though a great deal of skepticism as to the efficacy of this method of treating tuberculosis of bones and joints exists, the many excellent results that have been published go to prove that much of the skepticism is unwarranted. As v. Eiselsberg recently said (in reply to Mosetig-Moorhof in a discussion of this whole subject, after the latter had declared that this treatment should not be countenanced because it will occasion an acute dissemination of the infectious agent which will produce a rapid progressive extension of the local disease, and at the same time a rapid invasion of the whole organism), hyperemia produces good results in tuberculosis of the hand, elbow, and tarsus, even if it does not cure in all cases. This he has seen in his own cases and in those treated by Bier on a recent visit to the latter's clinic in Bonn. Kocher, in another recent discussion of this subject, speaks favorably of this method of treatment, and emphasizes the fact that complete immobilization is not necessary if Bier's treatment is followed. Habs, after testing this method in two hundred cases, gives a favorable verdict. In closed tuberculous joints results in his series are frequently astonishingly rapid. Some cases developed abscesses which Bier long ago called attention to, but these closed after incision. In open tuberculous cases Habs' results were less good. Luxembourg reports twenty-three cases and claims for the treatment that the end results are movable joints, whereas immobilization leads so frequently to stiff joints. In seven of his cases he obtained a cure; eight were improved. In these pain and swelling diminished; the granulations became healthy and the sinuses closed: seven cases were still under treatment, and in one case he failed completely. Tillmanns, Henle (Mikulicz), and many others recognize venous hyperemia as an effective method of combating the type of tuberculosis under discussion.

So much for the opinions of others; now let us turn to Bier's own publications. The method employed in my series of cases is the method that Bier worked out after years of experimentation. During these years he used less simple and much less effective methods, and it is probably due to the repeated changes in his technique that many have looked on the whole matter with skepticism.

At present Bier considers the following as contraindications to the treatment by hyperemia: Beginning amyloid changes, severe pulmonary phthisis, large joint abscesses, and marked malposition of the affected parts (knee). Here he advises operation. All other cases should be treated conservatively by venous hyperemia plus iodoform injections in hydrops and in purulent joint cases.

The results obtained by Bier in cases treated recently by his present method speak for themselves and will be cited *in extenso*:

Carpal tuberculosis—seventeen cases, fifteen cures. Three cases with perfect mobility, twelve with adequately good mobility, despite extensive bone disease. In four of the seventeen cases there were sinuses. In five cases abscesses had to be opened during the treatment. In two severe cases the condition was improved. Average duration of treatment was twelve months.

Tarsal tuberculosis—thirteen cases, eight cures. In three normal mobility and in five good mobility. Of the cures four were sinus cases; three cases were improved, one case unimproved; one case later came to amputation. Of the original thirteen cases eight were sinus cases. Average duration of treatment, ten months.

Tarsal tuberculosis—thirteen cases, eight cures. Of these two with normal mobility, one was stiff in good position, two cases improved. Of the original five cases two were incipient cases and one had fistulæ. Eight other cases did not respond to hyperemia treatment and came to resection.

Shoulder-joint tuberculosis—one case, one cure with normal mobility. From this synopsis it is evident Bier operated in these forty-four cases only eight times, and that the knee joint gives the poorest results with this method of treatment. It is also evident that the functional end-results are excellent, even though the treatment is a prolonged and painstaking one. That the end-results are permanent in many cases Bier shows clearly by citing three cases treated fourteen and fifteen years ago, and which remained well. His recurrences after this method of treatment, he declared at the International Congress of Surgeons, were no more nor no less frequent than after other methods of treatment. He is beginning to employ Klapp's suction hyperemia apparatuses in the treatment of the fistulous cases to assist the constriction hyperemia by their more localized action.

In other bone conditions venous hyperemia has a beneficial effect. In chronic nontuberculous osteomyelitis it may frequently save the patient from repeated extensive and minor operative procedures: I have seen exposed apparently necrotic bone at bottom of long sinuses cover over and heal in under this plan of treatment, after the same effect had been sought in vain by repeated operations. It is well known that such sinuses leading to dead bone often persist after necrotomies, and here I see a special field of usefulness for venous hyperemia.

That hyperemia has a marked effect on bone has long been realized. Without understanding the condition Ambroise Paré employed hyperemia to increase callus formation. Dumreicher and Nicoladoni revived Paré's procedure to prevent the formation of pseudarthroses. Helferich in 1881 used the type of hyperemia under discussion for insufficient callus formation after fracture; also in insufficient involucrum production after bone necrosis. Thomas has made use of it to obtain firm union in fractures.

Venous hyperemia to stimulate the formation of callus is consequently an old and well-proven method of hastening a cure in a condition which Nature usually takes care of by herself. That pseudarthroses are a not too uncommon occurrence the many

methods to overcome the same show all too clearly. Of all the simpler methods, such as rubbing the ends of the bones together, local injections between and about the fracture of tincture of iodine, or blood, etc., the method by venous hyperemia is one of the best and most efficacious. In one case of delayed union that I treated by this method I was surprised to find a rapidly forming periosteal callus where previously there had been practically no periosteal callus production. In this case the medullary callus was not strong enough to prevent abnormal mobility, and the periosteal irritation produced by this method of treatment led to the formation of a firm, copious periosteal callus, though almost five months had elapsed between the injury and the beginning of the treatment by venous hyperemia. Others, in addition to the authors above mentioned, have obtained similar good results with this method, but the cases being isolated ones they have not been published. I, personally, know of two such cases.

In addition to the above conditions of the soft parts and bones, I employed this venous hyperemia in a variety of superficial conditions and in neuralgias. In the latter, as in those vague conditions mentioned above, it frequently relieved. In superficial ulcerative conditions the results were not particularly encouraging. Habs, however, following Ritter, reports good results in freezing injuries. In nine cases he obtained rapid, painless cure.

That will give a fair idea of the conditions in which venous hyperemia produced by a firm application of the rubber bandage may be used with success. As will be seen, they are almost all chronic or subacute conditions. Last year Bier advocated the use of a "fiery red" hyperemia produced by a light application of the rubber bandage in the treatment of acute inflammatory conditions. Considerable practice is required to apply the bandage properly in these cases. To make this paper more complete I must refer briefly to this type of constriction hyperemia, as it seems destined to occupy an important place as a therapeutic agent in inflammatory cases that we can absolutely control. As I said above, this method demands mild congestion, a fiery red edema (with at times a blue tinge to the part), and many hours' continuous use.

Hardly a year has elapsed since Bier announced this method of treating acute inflammatory conditions. That the method is effective in such conditions the voluminous literature testifies, though the foundations are still not perfectly secure, nor are the limitations of the method as yet clear. Bier's original report was based on 110 acute and subacute suppurative processes. The bandage was so applied as to produce a fiery red edema. It remained in place ten hours in mild cases, twenty to twenty-two hours in severer cases. It must never cause pain. Between treatments the part is elevated to allow of the subsidence of the edema. Then, if necessary, a fresh treatment is instituted.

This method of treatment leads to rapid separation of unhealthy and dead structures from healthy. It preserves tissues which usually necrose, *e.g.* tendons. It causes absorption without pus formation in some cases; in others it converts hot into cold abscesses. At times it leads to pus absorption without incision. It relieves pain rapidly. Such are a few of the main observations Bier has made in cases of cellulitis, of joint infection, of acute osteomyelitis, and of tendon-sheath phlegmons.

The part involved in disease is moved passively to preserve the proper function and at the same time to squeeze pus out of the incisions or spontaneous (nondrained) openings. Bier adheres to the old doctrine of *ubi pus ibi evacuo,* but by means of venous hyperemia he is able to dispense with liberal incisions and gauze or tube drainage.

V. Brunn, Colley, Derlin, Herhold, Habs, Lossen, and Stich have reported their results with this form of hyperemia, which are, on the whole, favorable and in agreement with Bier's claims. Others have already elaborated the use of this type of hyperemia. Thus Keppler, Heine, and Stenger have employed it in acute otitis media and acute mastoiditis. In both the results have been decidedly encouraging and most surprising. Keppler has cured a whole series of cases that usually undergo an extensive operation. Hochhaus has applied this type of hyperemia to the throat, reporting good results in twenty-five cases of diphtheria. Renner has applied it in various eye diseases.

As will be seen, all these cases are of a much more acute type than those described in my series, and it is questionable whether they all should not be treated primarily in a hospital. In this country it will probably never be possible to treat cases of this gravity as they are treated abroad, and as long as dispensary cases are not amenable to this form of treatment I shall refrain from going into any further details along this particular line, keeping my experience in hospital and bed patients for some future time.

Having thus touched upon the three most important methods of producing passive congestion, a few words of attempted explanation of the phenomena above described are indicated. Bier originally used hyperemia in the treatment of surgical tuberculous conditions, and he was led to do so by the following observations made by clinicians and pathologists. Farre, Travers, Louis, Lebert, Eymann, and Frerichs had demonstrated that patients with stenosis of the pulmonary artery almost regularly developed a progressive pulmonary tuberculosis. As pulmonary stenosis leads to anemia of the lungs, it might be inferred that the anemia had a definite relation to the tuberculous invasion. Rokitansky's observations made this inference seem more than likely. He found in 143 cases of cardiac hypertrophy only fifteen instances of pulmonary tuberculosis, and in these fifteen cases the condition in the lungs was inactive, *i.e.* healed. Subsequent statistics based on autopsy reports did not wholly substantiate Rokitansky's publication. Still the fact that cases which clinically showed well-marked signs of valvular disease were relatively immune to pulmonary tuberculosis has gained general credence.

The apparent contradiction between the pathologists' and the clinicians' views is due to the fact that the former includes many cases under the title of valvular disease that the clinician does not recognize. Thus the term has a much broader application in pathological parlance. Naturally cases that present no clinical picture of valvular disease will not lead to congestion of the lungs, whereas those cases that are clinically recognizable will lead to such congestion. This congestion of the lungs, which occurs as well in spinal deformities as in valvular disease, Bier thought prevented the development of tuberculosis in the lungs, and in his application of this idea to surgical tuberculosis the whole edifice above considered was built up.

The simple observations that the congested lung of heart disease almost regularly excludes the development of tuberculosis in the lung is, however, far from an explanation of the process whereby the lung is rendered, so to speak, immune. From the facts previously described, in the first part of this paper, it is evident that artificially produced conges-

tion has a decidedly beneficial effect in a great variety of conditions in addition to its action in tuberculosis. Some explanation of this action has been given us by a series of careful experimentors and observers, chief among them being Bier, Ritter, Hamburger, Hofmann, Noetzel, Heller, Heile, Joseph, Penzo, and Rautenberg.

The results of all this work are so far-reaching and so important, so full of surprises to all those who still cling to the older conceptions of inflammatory processes, that I feel inclined to enter into this whole subject very fully, especially as our literature has taken very little note of these investigations. But lest this paper become too long and the practical part of it suffer, I shall present the results very briefly without going into the details of the work of the different investigators.

Two facts observed in the cases treated by hyperemia urgently demand an explanation. Why does congestion relieve pain? Why does this congestion prevent the progress of the disease or relieve the results of a previous disease?

We are accustomed to look upon the congestion as a harmful process. To diminish it we use antiphlogistic measures. Elevation of the part, application of cold, etc., are routine procedures. Now, Bier advises the opposite, and the results of such therapy prove how wrong our previous methods were. We are accustomed to look upon pain as the result of the hyperemia and of the swelling of the parts involved. Now, Bier shows us that this is an incorrect conclusion, as artificially produced hyperemia and edema relieve pain. It has become more and more evident that pain in these inflammatory conditions is the result of irritation of the peripheral nerves by concentrated exudates. Artificially produced edema diminishes this concentration, and, in addition, acts apparently similarly to Schleich's infiltration. Bier and Ritter have paid particular attention to the relation that obtains between pain and swelling. Both come to the conclusion that pain lets up as soon as swelling sets in, both in inflammatory and in traumatic conditions. All experiences with artificially produced hyperemia, whether venous or arterial, agree in this decided influence on pain, and it would seem that Ritter's explanation of this phenomenon is the most plausible.

The most important action, however, is the antibacterial. Hamburger lays particular emphasis on the fact that in the treated part there is an increase in alkalies and in carbonic acid both in the blood and in the lymph (of the edema). Both of these act as bactericides. Noetzel and Buchner emphasize the fact that there is a marked local increase in the number of leucocytes, and probably an increase in the alexins (enzymes). In addition, the artificial edema dilutes the local toxins, and, as Joseph has shown, it thus diminishes the effect of poisons. Heile has noted a marked increase in the excretion of purin bodies in patients under treatment, and refers this to the breaking down of numberless leucocytes. Hofmann has studied the effect of suction hyperemia on granulation tissue. As a result of the suction, the tissue spaces which were filled with infiltrating leucocytes were cleared of these. The vessels which were full of leucocytes became dilated, and the leucocytes became less numerous approaching the normal proportion to the red cells. The fluid drawn from the granulation tissue contains bacteria, leucocytes, red cells, lymphocytes, and a fine network of fibrin. A similar change probably occurs in the treatment of acute inflammatory conditions by constriction hyperemia, especially when there is an incision into the affected area and the edema serum escapes into the dressings.

Besides the analgesic and the antibacterial activity of localized artificial edemas, as we have seen, there is a nutritive and a resorptive influence inherent in this process. In the stimulation of the periosteum we see instances of the former, and in the loosening up of old adhesions instances of the latter.

As work along these lines progresses many more activities may be found underlying the process that Bier has revived. The study of the processes underlying the curative action of hyperemia will surely lead us to a new understanding of many of the problems connected with the pathology of inflammation, just as it has forced us to change our views as to the cause of pain in inflammation. While these theoretical questions will be slowly solved, the general adoption and practical application of Bier's method will, I trust, be a matter of the very near future.*

In closing I wish to thank the various gentlemen who have assisted me in taking care of the above cases. To Dr. Garrigan I am especially indebted.

SURGICAL DIAGNOSIS IN EMERGENCY WORK.

By WILLIS E. HARTSHORN, M.D.,

NEW HAVEN, CONN.

The writer's excuse for preparing a paper on this subject is that during a rather protracted hospital service nine months were spent as ambulance surgeon in one of the large New York City hospitals. The number of calls each day ranged from twelve on the average to thirty as a maximum rate, though during the time of extreme heat in summer they ran even higher than this. As the ambulance surgeon is held strictly responsible by the attending surgeon and hospital authorities, who in turn are held liable by the courts for any mistakes, the question of making a correct diagnosis many times under the most unfavorable circumstances becomes a most urgent one and requires the greatest care. In fact, the matter of proper attendance on ambulance cases at the present time has become so serious that most of the large hospitals allow only the senior members of the house staff to perform this duty.

The chief difficulty in diagnosis seems to lie between alcoholism and the various lesions of the skull, injuries to the trunk and extremities being as a rule quite evident, or accompanied by symptoms of such a character that mistakes in these instances are much less frequent. More cases of alcoholism are seen on ambulance duty than any other one thing, and the tendency of the ambulance surgeon when in doubt too often seems to be towards this diagnosis, resulting in the transfer of the patient to the station house instead of to the hospital. Occasionally one of these cases dies of fracture of the skull, to be diagnosed only on the postmortem table.

This mistake has given many a hospital a large amount of free advertisement of a most undesirable nature, and has cost more than one interne his position. The character of the cases seen on ambulance duty covers a wide range, which includes concussion, fractures of the skull, fractures of the extremities, alcoholism, epilepsy, apoplexy, opium poisoning, uremia, carbolic acid poisoning, illuminating gas poisoning, internal injuries, thoracic and abdominal, and the various minor lesions.

Taking up this classification more in detail, first to be considered is "concussion." In speaking of concussion from a clinical standpoint, we refer to that class of cases in which as the result of trauma the functions of the brain have been temporarily suspended. The patient is stunned and rendered more or less insensible for the time being. To this class often belong those cases in which an individual leaves his office or home in a perfectly normal condition and later is found wandering on the street dazed, with no memory of events occurring during a period more or less protracted. They are often very difficult to diagnose, only careful observation and time clearing up the most severe ones. Concussion does not necessarily occur from lesions inflicted on the head; a severe fall on the buttocks or on the feet may cause the same line of symptoms. Laceration of the brain is not, as a rule, the sequence of concussion, but

must be suspected in all the severe cases. The variety in the symptoms of concussion is great, varying from a simple sense of dizziness and temporary loss of sight to complete unconsciousness. A fall on the ice on the back of the head illustrates one extreme, while the knockout blow in the face is a more severe type. In a severe case of concussion the patient is found lying unconscious. This unconsciousness may be complete or incomplete. Some brief answers may be made to questions, but soon stupor intervenes. There is distinct evidence of shock. The pulse is weak, the skin clammy, the limbs cold, often there is free perspiration. The muscles are flaccid, but there is no paralysis. The temperature is usually subnormal. The sphincters are relaxed. The eyes are half open, with the pupils equal, generally moderately dilated, and as a rule responding to light, though somewhat sluggishly. On being called to see such a case a careful examination should be made by the ambulance surgeon into the history of the accident and the character of the substance producing the trauma. The head should be examined for any sign of injury, and contusions of the scalp carefully investigated. No lesion being found to indicate a fracture of the skull, the patient is to be kept under the most careful observation, time alone in many cases serving to clear up the diagnosis. The danger in the first stage in severe cases is collapse, during which death may occur from failure of the heart's action. After a period varying from a few hours to a day or more, the stage of reaction comes on. Vomiting is often the first sign of returning consciousness. The pulse becomes stronger, the color improves, and the patient's mental condition brightens, though he may complain of dullness and headache for many days. The one sign which remains to mark the condition is the entire loss of memory regarding the accident. It might be well to mention at this point that cerebral irritation is a condition which may follow an injury causing concussion, especially at the beginning of recovery. It usually indicates contusion or laceration of the brain or its membranes, or hemorrhage. The patient becomes restless, lies on his side, with the thighs drawn up and the legs flexed. He is very irritable. Urine and feces may be passed involuntarily. This condition either passes to rapidly-deepening coma and death or lasts for a number of weeks, when there is gradual recovery.

Compression.—Another class of cases is that in which the unconscious condition in which the patient is found is due to compression of the brain. Here the symptoms show certain differences which make it possible to detect the lesion. Compression may be due to a number of causes; the first and most common in emergency work is depressed bone, then come foreign bodies, hemorrhage, tumors, and inflammatory exudates. In compression we have a more serious lesion; the patient may be completely unconscious or the intellect simply dulled. In the former case the breathing is slow and stertorous. The pupils vary widely in their character; first contract and later dilate, often unequally. There is paralysis. Usually in traumatic cases this affects one side of the body first, and later, as the intracranial pressure increases, both sides become paralyzed. It is often almost impossible to differentiate between compression and concussion. The fact of paralysis in compression and its lack in concussion is the most important diagnostic point. Whenever there is a constantly increasing degree of stupor, with a gradual broadening of the paralyzed area, hemorrhage should be suspected and operative procedure be at once instituted. The point to emphasize is that the patient in all doubtful cases must be kept under observation, when the test of time will usually give certain symptoms which are absolutely diagnostic. When the symptoms of compression come on immediately after an injury, we may expect the cause to be either fracture or foreign body. In case the lesion is caused by a foreign body there will, of course, usually be an external wound, but a depressed fracture does not necessarily show this. An incised or lacerated wound of the scalp, with the history of a fall or blow on the head, accompanied with the signs of compression, should always be explored, and the bone beneath it carefully examined. The same thing is true of a contusion or a large hematoma of the scalp. Cases of depressed fracture without symptoms are more common in children than in adults. In small children the skull may be depressed to a very considerable extent and the child remain conscious. It is often difficult to diagnose a small depressed fracture simply with the finger, even when there is a comparatively large external wound, and a careful examination of the bone itself is usually necessary to confirm the diagnosis. The ridge in the periosteum is often mistaken for the outline of a depression in the bone. A fracture of the vault may be simply linear. In most cases of this class there are no further results from the injury. If the fragment of bone is depressed and there are symptoms of compression, it must be elevated. In many cases the inner table of the skull is fractured for a greater distance than the depressed outer fragment, and all these particles of bone must be carefully removed. If the dura is torn, its edges should be closely approximated with sutures of catgut in order to avoid all possibility of hernia cerebri. The length of time a depression may remain undetected after fracture of the skull and yet be operated on successfully after diagnosis is often considerable. Operative interference shows remarkable results. In many cases the mental condition of the patient clears up at once after the removal of the depressed fragments. If the brain is lacerated by pieces of bone the prognosis is, of course, graver.

Fractures of the Base of the Skull.—Fractures of the base of the skull are of a much more serious nature than fractures of the vertex. They are divided into fractures of the anterior, middle, and posterior fossæ.

Fractures of the anterior fossa involve the orbit, the ethmoid bone, and the lesser wing of the sphenoid bone. The symptoms are: First: Subconjunctival ecchymosis, with as a rule no blackening or bruising of the tissues around the eye. Second: There is often a prominence of the eyeball due to hemorrhage behind the eye. Third: In case the fracture is compound there may be an escape of brain matter into the wound. Fourth: When the ethmoid is involved continuous and profuse hemorrhage from the nose is the main symptom, and there is at times an escape of cerebrospinal fluid from the same point. Fifth: If the lesser wing of the sphenoid is fractured the optic and motor oculi nerves are apt to be involved. Sixth: If the frontal sinus is opened there is often emphysema of the areolar tissue of the anterior portion of the scalp.

In fracture of the middle fossa of the skull the principal symptoms are: First: Hemorrhage. This comes from the ear as a rule, though we may have in addition bleeding from the nose. When coming

from the ear it must be profuse and fairly constant. Lesions of the wall of the external ear or drum must be ruled out.

Simply a few drops of blood from the external meatus means nothing at all. When bleeding comes from the nose fracture of the pituitary fossa should be suspected. A good deal of blood from such a lesion will trickle into the pharynx and be vomited later on. Bleeding from the nose, however, should be accepted with a very great degree of reservation when we consider the numerous accessory sinuses. Second: Escape of cerebrospinal fluid through the ear is another very important symptom. We know then that the arachnoid has been torn and that there has been very probably a laceration of the brain substance. This latter statement can be substantiated if there is an escape of brain matter through the external ear. The pouring out of the cerebrospinal fluid may amount to ounces. Third: In fracture of the middle fossa we may look for some paralysis of the facial muscles. The uvula is often drawn to one side. There may be deafness from injury to the auditory nerve.

In fracture of the posterior fossa of the skull there are comparatively few definite physical signs. There may appear deep-seated ecchymoses of the muscles of the neck or a swelling of the tissues in the mastoid region, or a bulging forward of the posterior pharyngeal wall. In general it can be said that in fracture of the base of the skull the patient lies unconscious and cannot be roused. He mutters to himself, turns from side to side, rubs the head with the hand in case there is cerebral irritation. The pupils are often unequal. The breathing varies, but is stertorous in the severe lesions. The amount of paralysis is usually limited to the cranial nerves. It may become more extensive, however.

Differential Diagnosis.—In connection with the diagnosis of concussion and the fractures of the skull in emergency work must also be considered the question of differential diagnosis. Alcoholism, epilepsy, opium poisoning, uremia, and heat prostration all must be ruled out. In many cases there is, of course, an injury to the scalp. This may as well occur in alcoholism as in fracture, and too much reliance cannot be placed on it. The odor of whiskey may be detected in a patient's breath, and yet he may not be in a state of coma due to alcoholism. Deep pressure on the supraorbital nerves will rouse a man from an alcoholic stupor. There is no paralysis in alcoholism. The pupils are usually contracted, dilating when the patient is aroused. Washing out the stomach will often aid in the diagnosis.

Apoplexy.—In apoplexy there is absolute unconsciousness, stertor, hemiplegia, strabismus, and puffing of the cheeks during respiration.

Opium Poisoning.—Opium poisoning shows pinpoint pupils, no paralysis, and very slow respirations. At times the odor of the drug can be detected in the breath.

Uremia.—In uremia there is no paralysis. There is apt to be edema of the extremities, and on drawing off the urine we find a large percentage of albumin. There is often the peculiar uriniferous odor to the breath. Examination of the optic nerves will clear up the diagnosis in some cases. There is high tension to the pulse.

Epilepsy.—In epilepsy the patient must be kept under observation, but usually becomes conscious in a comparatively short space of time. A history of previous attacks will clear up such a case. Scars on the tongue or other portions of the body should be carefully looked for. There are spasmodic movements of the extremities, frothing at the mouth, and cyanosis during the acute stage of the attack.

Heat Prostration.—Heat prostration must be diagnosed by the character of the weather, the temperature of the patient, and the environment under which he has been working. The face is flushed, the pulse full and bounding, the pupils contracted, the eyes bloodshot, and the skin hot to the touch. There is absolute unconsciousness.

Fractures of the Extremities.—No paper on the subject of emergency work would be complete without at least a brief mention of fractures of the extremities. The ambulance surgeon sees in the course of a few months' emergency service more cases of this class than he will probably meet in the first ten years of his private practice. Here is an opportunity too often neglected for securing proficiency in the treatment of fractures and skill in their diagnosis. Too often these cases are rushed to the hospital with but a superficial examination, and with splints so carelessly applied as to cause the patient the greatest degree of discomfort. The period immediately after a fracture has occurred before the swelling incident to the severe contusion and laceration of the soft parts has obscured the lesion to the bone offers the most favorable opportunity for diagnosis, and a careful examination should be made as soon as the case is seen. Misplaced fragments of bone can be discovered at this time which cannot be detected later on.

Injuries to the Thoracic and Abdominal Viscera.—Another important class of cases and one with which the ambulance surgeon comes into close and frequent contact is that associated with injuries to the thoracic and abdominal viscera.

Under the heading of injuries to the thoracic wall and viscera should be included: A.—Penetrating wounds of the chest wall and pleura. B.—Penetrating wounds of the chest wall pleura and lungs. C.—Penetrating wounds of the pleura, pericardium, and heart. D.—Penetrating wounds of the pleura and diaphragm. E.—Crushing injuries to the sternum and ribs.

Stab wounds and bullet wounds may simply penetrate the pleura, or may pass through the pleura into the lungs. Pneumothorax is always the result when there is an inrush of air into the pleural cavity. In case the lung itself is perforated, especially if the external wound into the pleura is occluded and the air cannot escape, we have the formation of a subcutaneous emphysema. This is usually limited to the region of the wound, but may extend to the thoracic wall, and even to the entire body. It is more common in penetrating wounds of the pleura than in any other class of injuries, and is always diagnostic of puncture of the lung. Crushing injuries to the sternum and ribs are often very severe. A fractured rib may perforate the lung, and here, too, we may have subcutaneous emphysema with the expectoration of bloody mucus and difficult breathing. The diagnosis in most of these lesions is comparatively easy. It should always be remembered, however, that a penetrating wound of the chest wall may perforate the diaphragm and cause a serious lesion to some of the abdominal viscera.

Internal Injuries Involving the Abdominal Content.—No more difficult task confronts the surgeon performing emergency duty than the correct diagnosis of the different internal injuries to the abdominal viscera. In the order of the frequency of their occurrence we may classify them as: A.—Penetrating wounds of the abdomen including gunshot wounds and stab wounds. B.—Severe contusions the result

of falls and other forms of external violence causing lacerations of the viscera. C.—Injuries to the pelvic viscera, including fractures of the pelvis in so far as they relate to such lesions.

A.—Penetrating Wounds of the Abdomen.—In the diagnosis of penetrating wounds of the abdomen, the first question to be considered by the ambulance surgeon is whether he has to do with a wound which really penetrates, or one which is superficial and only passes through the muscular layers of the abdominal wall. A protruding piece of omentum may settle the question at once; but as is more commonly the case, it is necessary to take the patient to the hospital and there insert a probe into the wound under all possible antiseptic precautions, when a diagnosis can usually at once be made. Having determined that the wound does penetrate the abdominal cavity, the question at once arises whether it has perforated important viscera or not, whether there is immediate danger from hemorrhage, and whether the patient's condition will warrant operative interference.

B.—Injuries to the Abdominal Viscera.—Equally important are lacerations of the abdominal viscera caused by trauma. These often produce no external lesion by which their diagnosis can be determined, therefore this class of injuries present even greater difficulties to the ambulance surgeon than do stab wounds or other penetrating wounds. In general the symptoms of internal lesions coming under this class are: (1) Shock. This is unusually marked. Wherever there is shock with the history of traumatic injury, which does not present any external signs of violence, a lesion of the abdominal viscera should be suspected. (2) Abdominal rigidity. This is one of the most important symptoms of this class of lesions, and may be considered almost pathognomonic. Some surgeons attach so much importance to rigidity that they operate when this symptom alone is present, if accompanied by severe shock. It occurs in lead colic and in the various inflammatory lesions causing peritonitis. In these cases there is, of course, no history of trauma. (3) Hemorrhage, with the accompanying weak and rapid pulse. Hemorrhage when present with rigidity is at once an indication of internal injury requiring operative interference. (4) Pain. Pain referred to the location of the injury is usually present. (5) Tenderness. Tenderness on pressure over the area where there is rigidity is a very common symptom. (6) Tumor. Tumor indicative of the presence of fluid due to hemorrhage is frequently noted, especially in the flanks, following injuries to the spleen and kidneys.

Classifying these symptoms more concisely and localizing them more closely to the viscera occupying the anatomical divisions of the abdomen, we will consider then, even at the expense of some repetition.

First.—The Liver.—A laceration or a penetrating wound of the liver will produce: (1) On palpation, pain and tenderness in the right hypochondriac or epigastric region, depending on which lobe is involved. (2) Abdominal rigidity in this region. (3) Shock. (4) If there is hemorrhage, a rapid and feeble pulse.

Second.—The Right Kidney.—A similar lesion of the right kidney will produce: (1) On palpation, pain and tenderness located further towards the right flank than when there is an injury to the liver. (2) Rigidity in the right hypochondriac and right lumbar region. (3) Frequently a hematoma in this region, with dullness on percussion. (4) Hemorrhage from the kidney through the ureter, as indicated by the presence of blood in the urine on catheterizing the patient. (5) Shock. (6) Escape of urine from the wound in the kidney will cause a large area of flatness in the right flank over the kidney. (7) The escaped fluid is usually retroperitoneal.

Third.—Stomach and Intestines.—Usually the inuries to these viscera are of the perforating type. The fact that a wound penetrates the abdominal wall makes an injury to the contained organs extremely probable, and an exploratory operation is always indicated, delay only increasing the danger of peritonitis. The immediate symptoms of perforation of the stomach or of the intestines are: (1) Shock, with a weak, rapid pulse and an anxious expression to the face. (2) Abdominal rigidity, later distention. (3) Abdominal pain and tenderness, which may be very general. (4) The vomiting of blood in case there is perforation of the stomach. (5) Blood in the stools when the perforation is low in the intestinal canal. (6) On palpation no tumor can be detected. (7) Great variation in the amount of hemorrhage. It is not so generally present as in lesions of the solid viscera.

Fourth.—Left Kidney and Spleen.—The symptoms are similar to those enumerated under the right kidney, with the exception that an injury to the spleen will of course not produce, as in the case of the kidney, blood in the urine. The tumor caused by the hematoma will be higher up in its relation to the diaphragm, more difficult to palpate, and not so extensive as in a kidney lesion, as the blood will not be mixed with an escape of urine.

Fifth.—Laceration of the Omentum or Mesentery.—A laceration of the omentum or mesentery may cause symptoms simulating an intestinal lesion. In some cases the hemorrhage is so severe as to produce results as serious as those following laceration of the more important viscera, with the attendant abdominal rigidity, shock, and weak pulse.

C.—Of equal importance to the lesions of the abdominal viscera above-mentioned are injuries to the pelvic viscera and to the pelvis.

The Bladder.—Either a penetrating wound, a laceration, or a rupture may be the result of trauma to the bladder. Any one of these may be extraperitoneal or intraperitoneal.

If extraperitoneal, the symptoms leading to the diagnosis are as follows: (1) The history of the accident, usually a severe crushing force. (2) Pain in the region of the bladder. (3) Abdominal rigidity in the hypogastric region, with marked shock. (4) Intense pain on attempting the act of micturition. Frequent desire to micturate. (5) Extravasation of urine. The direction which the urine takes depends on the location of the injury. It may extend to the cellular tissue between the bladder and the rectum if the tear is posterior, or above the pubis, even as high as the umbilicus if it is anterior. It may pass anterior to the peritoneum, to the iliac and inguinal region, forming a tumor there, or extend to the thighs and scrotum by way of the obturator foramen, the inguinal canal, or the femoral ring. (6) Blood in the urine on catheterizing the patient. (7) The oozing of blood from the urethra. (8) The catheter can often be passed its entire length into the urethra, entering through the tear in the bladder wall the space of Retzius, if the rent is anterior, or the

cellular tissue between the bladder and the rectum if it is posterior.

If the tear is intraperitoneal, the symptoms presented differ somewhat from those of an extraperitoneal lesion. In addition to pain in the region of the bladder and on urination, abdominal rigidity, shock, the presence of blood in the urine, and the oozing of blood from the urethra, there will be: (1) Abdominal distention, moderate at first, but gradually extending. (2) Extravasation of urine into the abdominal cavity. This does not necessarily mean peritonitis, at least not for from twenty-four to thirty-six hours, if the urine is aseptic and there is no cystitis, for the peritoneum has a remarkable power for the absorption of aseptic fluids. (3) The passage of the catheter directly into the peritoneal cavity through the rent in the bladder wall. (4) There is no extravasation of the urine into the cellular tissues in the vicinity of the bladder. This usually occurs within a few hours after an extraperitoneal rupture, and is an important point in making a differential diagnosis, which at best is necessarily very difficult.

The Urethra.—Another lesion which is closely associated with the bladder is rupture or laceration of the urethra. It is often difficult to diagnose this from a tear in the bladder wall, particularly if this be of the extraperitoneal type. A ruptured urethra does not necessarily require a traumatic injury for its cause. It may be the result of a pathological process which weakens the integrity of the urethral wall to such an extent that it gives way under a sudden strain. The symptoms of a ruptured or lacerated urethra are as follows: (1) Retention of urine, partial or complete, depending on the severity of the lesion, usually complete. (2) Extravasation of urine, which rapidly increases in extent, involving the scrotum and spreading down the thighs, with discoloration of the skin. (3) There may be present a painful swelling in the hypogastric region, tender on palpation and representing the overdistended bladder. (4) The catheter cannot be passed into the bladder. (5) Perineal tenderness, with ecchymosis and swelling. (6) Oozing of blood from the urethra. (7) Pain.

A torn urethra is one of the most difficult lesions of the genitourinary tract to treat successfully, and the importance of an early diagnosis cannot be overestimated.

A discussion of injuries to the pelvic viscera would not be complete without mention being made of the important fact that fractures of the pubic bones are a very common cause of traumatism to the bladder and the urethra. The ambulance surgeon should bear in mind this important possibility whenever an accident involving these structures occurs.

1138 Chapel Street.

Fourth of July Tetanus.—The *Journal of the American Medical Association* publishes in the issue of August 18, 1906, reports of 89 cases of tetanus resulting from Fourth of July injuries this year, of which 75 cases were fatal. Antitoxin was more generally used than ever before. Its chief value, apparently, is as a prophylactic. After the main symptoms of lockjaw have begun, it seems to have little value, since in only three cases out of 89 are patients reported to have recovered. In one of these, which was very persistent, antitoxin was administered as often as ten times each day, with recovery as the result.

PNEUMOTHORAX, WITH A REPORT OF FIFTEEN CASES.*

By J. N. HALL, M.D.,

DENVER, COLO.

This condition is so commonly overlooked that I wish to report the results of my study of fifteen cases seen during the past four years, and to call attention to its signs and symptoms, which ordinarily make it easily recognizable if the possibility of its existence only be thought of. Twelve of these cases were seen with other physicians, while three were in the Denver City and County Hospital. Eleven were males, four females. The youngest was ten years, one thirteen years, the oldest thirty-four years, and ten were between twenty and thirty years.

The cause was tuberculosis in eleven cases, in two of these in conjunction with attacks of acute pneumonia. In the boy of ten it followed a bronchopneumonia. One case occurred from the wounding of the lung by the needle used by a house physician in injecting antistreptococcic serum for a supposed sepsis, the real cause of the chill being an acute pneumonia, followed by crisis on the ninth day, and an empyema later—a pyopneumothorax. In two cases the pneumothorax was due to gunshot wound of the left chest, hemothorax being also present.

Eight of the cases were upon the right and seven on the left side of the chest, although the left side was affected in twenty-nine out of forty-four cases reported by Morse, and is said in general to be more often affected.

One case of gunshot wound ended promptly in recovery, and one went on to a fatal termination in about twenty-four hours, more from the hemorrhage from wound of vessels in the lung than from respiratory embarrassment. The boy of ten just mentioned recovered promptly after operation, exactly as one with postpneumonic empyema would be expected to do. All of the others died excepting the girl of thirteen years. This was a chronic case in connection with tuberculosis of the right apex, seen with Dr. Teele. An extensive necrosis of the right humerus demanded operation, but her general condition was so bad that I advised tonics and good feeding, with the possible hope that she might gain sufficiently to justify operation. She weighed but fifty-five pounds on April 23, 1904. The right chest was some two inches larger in circumference than the left, and was hyperresonant. The heart was displaced to the left, and beautiful coin sounds were to be heard over the right side of the chest, with metallic tinkling. There was scarcely any respiratory sound upon the right, nor was the voice to be heard. Large veins crossed over the right shoulder from the necrotic humerus, but no sign of tumor could be made out. I believe their distention was due to the pressure of the air in the chest upon the right subclavian vein, or possibly to pressure from enlarged tuberculous glands within the chest. One year later the signs of air within the chest had disappeared, and she had gained five and one-half pounds. I believe she had had a closed and noninfected pneumothorax, and that it recovered. Dr. Freeman operated May 3, 1905, upon the necrosis, and the girl has been doing well since.

Of the twelve fatal cases ten died within two months from the discovery of the pneumothorax. One lived probably four months, and one was operated upon at the Denver City and County Hospital and lived eighteen months. My past experience

*Read before the Denver City and County Medical Society, May 1, 1906.

would lead me to believe that in any large series of tuberculous cases a greater percentage than above indicated would live more than three or four months.

In six cases from one to five aspirations were done to relieve the dyspnea and general distress. No operation was advised in seven cases. In one case Dr. Whitney established permanent drainage into a bottle after Bülau's method, this being the patient that lived eighteen months. In the case due to puncture of the lung with the needle the temperature was up to 105° when I saw her, pulse 160, and respirations very rapid. Immediate drainage was advised, and although Dr. Williams, who was called in to operate, promptly evacuated two quarts of stinking pus, the young woman failed to rally from the operation.

In seven cases pus was present with the air in the pleura, and in one case only air was evacuated, although, doubtless, pus was also present. Dr. W. C. Mitchell reported myriads of pneumococci in the case following bronchopneumonia. In two cases following gunshot wound blood was evidently present. In four of the remaining five cases, fluid, without doubt purulent, was present, for they all died within a short time with the usual hectic. The remaining case is the one of the girl thirteen years old, in which I believe air only existed in the cavity, no infection occurring so far as I can tell. In several of the cases the first aspiration showed only a turbid serum, but it always became more purulent later, in the cases again aspirated, as is the rule. Aspiration was done only when demanded by the large size of the effusion, for, unfortunately, it does not seem to be curative. The fluid seems to be almost always infected in the tuberculous cases, doubtless from pus organisms carried in from the ruptured bronchus.

Of the ordinary signs of pneumothorax, or, more properly speaking, of pyopneumothorax, we find that splashing has been present in thirteen cases, not tried for in the more serious gunshot case, because of his desperate condition, and stated to have been absent in the girl of thirteen. The sign is so constant, so easily obtained, and so entirely reliable that it should be more often tried for than it is when percussion draws attention to any peculiarity within the chest not easily explained.

The heart was notably displaced in the opposite direction in all but one case, the average displacement being a little over three inches. In one case it was seven inches, in two, six inches each, and in three cases but one inch. In the case without displacement an old fibroid phthisis at the left apex had drawn the heart an inch to the left and the subsequent left-sided pyopneumothorax was not able to displace it to the right. Doubtless firm adhesions existed. This was the case drained by Dr. Whitney, after I saw him, in the Denver City and County Hospital.

In the cases with but little displacement doubtless old adhesions interfered with the mobility of the heart. The coin test and tinkling are each noted as positive in three cases, but, unfortunately, no record was made in most of them. One of the other of these two signs, if not both, may generally be elicited.

Notable cyanosis was present at the time of my visits in thirteen of the cases, there being none in the gunshot case that recovered, nor in the girl of thirteen.

Rapid pulse was a practically constant feature. In the gunshot case just mentioned the rate was 100, but no other record was below 120 per minute. The lowest respiration rate noted was 24 per minute. The temperature was generally elevated, but was doubtless more influenced by the tuberculosis or an associated infection than by the pneumothorax in most cases.

Exact measurements of the two sides of the chest are not recorded in many cases, but an increase of one or two inches upon the affected side was present in several of them, marked and easily demonstrated.

Change of the level of fluid when present, upon change of position, is practically always to be noted, and I should rank this sign along with splashing, dislocation of the heart, tinkling, and the coin test. It is to be demonstrated also in simple pleural effusion without pleural adhesions, but with much less freedom of movement. In a case of subphrenic abscess succeeding suppurative appendicitis, recently seen with Dr. Freeman, the movable dullness was present, but was beneath the liver dullness, and thus caused no confusion.

The frequency of sudden pain and dyspnea I have not noted. In a few cases the rupture into the pleura is so sudden and the pain and dyspnea are so severe that we may date the trouble from the moment of such pain. In a large part of the cases I have been unable to fix the exact time of origin, however.

In two of the tuberculous cases complicated with acute pneumonia I am unable to say whether the pneumothorax came from ulceration through the wall of a tuberculous cavity or of a postpneumonic abscess. The fact that the pus was sterile in one of these cases leads me to believe it to have been from the tuberculosis rather than from the pneumonia. In the second case thick pus was drawn by needle from the base of the left chest, and air mixed with bloody serum from the fifth space, near the left nipple. I believe that a true empyema existed below and a tuberculous pneumothorax above. In the third case in which pneumonia was present the puncture of the lung by a needle, as described, was alone responsible for the pneumothorax.

The most interesting case of the series was that of a boy ten years, seen with Dr. Bartholomew. He had had a left lobar pneumonia, followed by crisis on the seventh day. Five days later he was again taken sick, and had a bronchopneumonia upon the right side. Dr. Bartholomew found fluid two weeks later and withdrew four ounces of serum and some air, a pneumothorax, doubtless due to rupture of the pleura over a bronchopneumonic focus, having occurred. Many pneumococci were found in the fluid by Dr. W. C. Mitchell. All the usual signs of a pneumopyothorax soon developed, and were most marked when I saw him. Resection of a rib and drainage resulted in prompt recovery.

To avoid overlooking this complication I think one must practise careful percussion habitually, as is true likewise if we are to avoid missing the diagnosis of transposition of the viscera, a condition probably more common than usually supposed, since I have seen four instances in the past ten years. It takes long practice to locate the heart dullness with fair accuracy, but when the art is learned these two conditions mentioned are almost certain of discovery. Every case of pneumothorax has marked cardiac displacement, unless the heart be adherent or the effusion of air be small. Displacement of the heart and mediastinum, in the absence of the usual causes, such as pleural effusion, or shrinking of the apex of one lung from fibroid disease, should lead one to search for unusual resonance on one side, depression of the diaphragm on one side, the presence of movable dullness from the fluid, which is nearly always exuded, for splashing, tinkling, falling drop sound, the coin test, and enlargement and immobility of the affected side. The conspicuous absence of breath and voice sounds and fremitus, the dyspnea, cyanosis, rapid pulse, and general distress all combine to make an easily recognized picture, once our attention is properly drawn out. Acute dilatation of the

stomach with a great amount of gas, subphrenic abscess containing air, and diaphragmatic hernia would be excluded without especial difficulty if their possibility were only recognized. I know of one case where a perfect history of the sudden pain and dyspnea, occurring while on the train, in a consumptive coming West, should have rendered the recognition of pneumothorax easy, yet a physician in another State who had seen much tuberculosis made a diagnosis of unilateral emphysema; a mistake of especial interest to me, since I had made the same error when a student.

In a case of a man with empyema following acute pneumonia (not here included) long neglected before being sent here for treatment, and dying three hours after I saw him, we found post mortem, gangrene of the left side of the diaphragm, and two quarts of stinking pus in the left pleura, with a colon bacillus infection. A small amount of gas, due, we believed, to the action of this organism, was present, but not diagnosed during life. Biermer and Senator believe that pneumothorax is occasionally caused by bacterial activity.

Although no such cases are included in this report, I have seen two or three instances of partial limited pneumothorax, where adhesions of the pleura prevented the usual development of the condition, and yet made a most perplexing set of physical signs. A specimen was recently shown at the Denver Clinical and Pathological Society by Dr. Sewall in which a very large part of the lung was excavated, so that a mere shell of lung tissue remained, and in this case a diagnosis of limited pneumothorax would apparently have been almost justifiable.

No cases were noted from whooping-cough, strain, emphysema, gangrene, or abscess of the lung. In several cases in which abscess of the liver, and in three in which suppurative processes traveling upward from the appendix, ruptured through the lung, it was evident that firm pleural adhesions had prevented the development of either empyema or pneumothorax. In one case of neglected empyema rupturing in or near the fifth right interspace in front there was no evidence of the admission of air. It is a curious fact that when the pus of an empyema is coughed up air so rarely takes the place of the ejected pus, for I cannot recall ever having seen it in sufficient amount to be diagnosed.

Treatment.—I believe in all cases beginning abruptly a moderate-sized dose of morphine should be given hypodermically, for the pain and dyspnea are severe. In traumatic cases of hemopneumothorax an expectant plan is probably best unless evidence of severe continued hemorrhage forces us to intervene surgically. Acute and infectious forms of the disease from gangrene, abscess, and pneumonia are probably best treated as if they were cases of ordinary empyema, especial care being taken as to anesthesia, and a local anesthetic being used if cyanosis and dyspnea demand.

In the cases following exertion, cough, and trauma, if the cyanosis and dyspnea demand relief, the abstraction of a small part of the air, so that the heart may move partly back to its place, gives great relief, but experience shows that it is best not to withdraw too much. In tuberculous patients only great dyspnea should lead us to aspirate, for the patients commonly decline more rapidly afterward than before. I have made the error of withdrawing so much of the serous fluid in these cases as to open up a valvular pneumothorax which had been closed, so that the relief obtained was very slight and of short duration. The prognosis is bad in any event.

URETHRAL DIVERTICULA AND CUL-DE-SACS.*

By NOAH E. ARONSTAM, M.D.,

DETROIT, MICH.

PROFESSOR OF DERMATOLOGY IN THE MICHIGAN COLLEGE OF MEDICINE AND SURGERY; MEMBER MICHIGAN STATE MEDICAL SOCIETY, MEDICO-LEGAL SOCIETY (NEW YORK), ETC.

URETHRAL diverticula and cul-de-sacs are anomalies of development, and are by no means so rare as some authorities would lead us to believe. The literature on this subject is, unfortunately, meager, and the little information one does gain on perusing it is very inadequate, so that one is tempted to regard the defects at best but as extremely infrequent ones affecting the urethral mucosa. Genitourinary surgeons of extensive experience have treated the subject in a very perfunctory manner and have paid but little attention to it in textbooks or otherwise. The reason why these urethral malformations are not more often encountered may be explained by the fact that they give rise to little inconveniences in the patient under normal conditions, and are only accidentally discovered during the examination of the urethra for some other malady. As already intimated, the author, finding nothing of interest recorded in the literature, had to rely solely upon his own resources in the elaboration and description of the subject designated by the title. This article is largely based upon a number of cases witnessed in both private and dispensary practice.

There are two forms of these urethral peculiarities, viz., (1) the *diverticulum,* a short, linear, narnow, collapsible pocket opening into the urethral canal, from one-fourth to one-half of an inch in length, of the caliber of a knitting-needle, unyielding, and nondilatable; and (2) the *cul-de-sac* proper, a larger, longer, and more distended pouch, stopping abruptly, or, rather, terminating blindly in the mucous lining of the urethra, seldom exceeding one inch in length, and somewhat larger in caliber than the preceding one. Both of these varieties are congenital anomalies, rarely found further down than the first two inches of the anterior urethra, and are in most instances situated on the floor of the canal, thus distinguishing them from enlarged and patulous urethral follicles, that are commonly located in the roof of the urethra, in proximity to the fossa navicularis.

Of interest to the histologist is the embryological phase of these small developmental errors. The only plausible theory the author is able to venture regarding their embryonic evolution is the faulty closure of that part of the genital cleft concerned in the formation of the urethral tract synchronous with faulty or delayed participation in the development of the epiblast lining it. Instead of the embryonic units blending at the proper period, they undergo a process of interrupted or faulty development and eventuate into the above-mentioned abnormalities of the urethral wall. As remarked before, they are only accidentally detected either on direct inspection and by means of the urethroscope, or as a result of urethral instrumentation in the form of sounds or similar instruments employed for therapeutic or diagnostic purposes. They are apt to engage the point of the advancing instrument, and if the operator still persists on meeting these obstacles in forcibly propelling the sound, he may not infrequently lacerate or even perforate the blind extremity, and thus establish a channel of communication between the *cul-de-sac* and the urethral canal.

* Read before the Section on Surgery of the Michigan State Medical Society, May 24, 1906.

As mentioned elsewhere, these anomalies give rise to little discomfort, but when once the seat of inflammatory involvement they may prove annoying and exceedingly rebellious to treatment, unless they are radically attacked by the method the author is about to outline. These anomalies may occasionally produce very vague symptoms, which are apt to puzzle the physician. They may, for example, simulate a mild case of urethritis, while the history and accompanying symptoms do not at all warrant such a diagnosis. They are, moreover, the cause of many a case of prolonged urethral discharge, a veritable "urethrorrhea," as it is termed by some, while microscopical examination reveals nothing of importance that could furnish a clue to the existing pathological state. Among other symptoms occasioned by them in a number of instances, painful micturition and urinary tenesmus may be pointed out. Should they become implicated in a gonococcic process concomitantly invading other portions of the urethral tract, they may form the starting point for strictures of various descriptions, particularly that of the longitudinal or bandlike type. They may also prove a prolific source of protracted suppuration, which is persistent and stubborn and does not seem to yield to the most painstaking and thorough treatment until the real cause of the malady is perchance discovered. The urinary stream in cases of urethral diverticula is irregular, either radiating and bifid or thin, rotating, and spirting and necessitating some effort on the part of the patient to expel it. This is falsely attributed to the presence of a stricture, and the patient is erroneously treated for such. Should the sound, which is chiefly used for the latter condition, happen to be of small size, it may promptly engage in the opening of the pouch or diverticulum and refuse to advance, when the exact nature of the lesion may be readily ascertained. Many more symptoms may be detailed, but the above are the main ones that demand our attention.

The *treatment* of these urethral defects is decidedly simple. It consists in first discovering the precise location of the sac or canaliculus by means of the urethroscope, or, if this be not available, of a small sound or probe; or a very fine olivary bougie may be used. With the former in position, the lacunar fold is then slit open with a small knife or tenotome throughout its entire extent to the very bottom of the urethral mucosa. Or, after the site of the channel or sac has been located, a urethrotome may be introduced, and by a sweep of the delicate blade the pocket can be divided. Local anesthesia usually suffices to accomplish this result. As soon as the fold of mucous membrane has been severed this should be immediately followed by the insertion of sounds in ascending sizes until the largest can be conveniently passed and left *in situ* for at least ten minutes each time. This must be continued for a week or ten ways to prevent the premature closure or healing of the divided edges or subsequent fibrous contraction, which may ultimately lead to stricture formation. Rarely is the fold of mucous membrane so extensive as to require ablation or removal *in toto*. The two lateral bands become eventually atrophied and level with the urethral canal.

Another method that may be utilized consists in the dilatation of the urethra either by means of a urethral dilator, or, what is still simpler, with a pair of ordinary dressing forceps gently introduced and expanded to its utmost limit (provided, however, that the *cul-de-sac* be not situated too far posteriorly), severing the band by means of a small scissor, and then proceeding in the manner delineated above.

In conclusion I wish to emphasize the rule, that in all cases of chronic urethral discharge without any appreciable or assignable cause or lesion as a basis, one must always be on the lookout for these annoying little anomalies and institute a thorough investigation for their possible presence.

106 East High Street

A NEW MANAGEMENT OF OCCIPITOPOSTERIOR POSITIONS OF THE FETAL HEAD.*

By M. C. O'BRIEN, M.D.,

NEW YORK.

OBSTETRIC SURGEON MISERICORDIA HOSPITAL.

Obstetric writers, commenting on the management of occipitoposterior positions, advise temporizing, in the hope that the malposition will rectify itself. * * * When it is found that the fetus oscillates before engagement, it may be assumed that the cord is wound about the neck or body, and is correspondingly shortened, and the head slews around with each uterine contraction, until the parturient canal dilates sufficiently to permit the head to descend. * * * If it engages in the occipitoposterior position, and manual reposition is employed, it will be found necessary to rotate the occiput in a three-quarter arc of a circle in order to bring the head in direct line with the body and to flex the chin. But if the accoucheur, failing to appreciate the true position, rotates in the opposite direction, he cannot retain the occiput in its new place, for as soon as the hand is withdrawn, the occiput reoccupies the vicious position, because the body does not rotate with the head. If this maneuver is repeated and forceps applied, the traction on the child's twisted neck is serious in its consequences, and it is a painful picture, when the forceps are removed, to see the black and bloated face "restitute" upwards and the maternal tissues gape in silent reproach for the attendant's incompetency.

To apply forceps to an occipitoposterior and rotate the head, like turning a screw on a bolt, with a pincers, is dangerous and unscientific, if not worse.

Version has largely superseded the above-mentioned methods, and no one will deny that, however skilfully performed, podalic version is a serious operation for mother and child.

Recognizing the facility with which the fetus slips about *in utero*, in all stages of labor, and assuming that the accoucheur's hand may pass where the child's body is to be extruded, I introduce either hand, under the occiput, with or without anesthesia (according to circumstances), grasp it firmly, separate the middle and ring fingers, to steady the neck, make counterpressure upon the fundus, thus bringing the fetal body and head into one solid mass, and with assistance slowly rotate the *mother* to the genupectoral posture. This manipulation brings the occiput anteriorly without traumatism to mother or child. Labor proceeds as when the patient is placed in the genupectoral position for prolapsed cord or in the lateral obstetrical posture as practised by the English school.

An awkward moment occurs when the patient's knee passes over the accoucheur, for the crux of the manipulation is to keep the head fixed steadily with the body curled upon it.

*Extract from a paper and demonstration before the Harlem Medical Association, May 2, 1906.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 25, 1906.

MAGNESIUM SULPHATE AS AN ANESTHETIC.

IT has recently been determined by Meltzer (MEDICAL RECORD, December 1905) that certain magnesium salts when injected subcutaneously or directly into the circulation, or when applied to the nerve trunks or spinal cord, inhibit nerve impulses and seem to manifest a selective action for nerve tissues. Death in the experimental animals, moreover, was found to be due in all cases to paralysis of respiration alone, no depressing action on the heart being observed. Encouraged by the striking and apparently harmless effect on the lower animals, Meltzer was led to recommend the use of this agent in the production of anesthesia for surgical operations on human beings and it has thus far been employed in twelve cases by Haubold, Willy Meyer, and Blake. The latter makes a general report of the results obtained (*Surgery, Gynecology, and Obstetrics,* May, 1906) which affords some basis for judging the value of the method. The dose employed in nearly all the cases corresponded to one cubic centimeter of a 25 per cent. solution of magnesium sulphate to every twenty to twenty-five pounds of body weight. The operations included appendectomy, curettage, perineorrhaphy, hernia, abscess incision, fistula in ano, and the reduction of a Potts' fracture—quite a miscellaneous array. In a few cases a small amount of chloroform was given as an adjuvant. The anesthesia induced by the method was characterized by considerable variability, and in two instances no anesthetic effect was noted, both these patients being alcoholics. The motor symptoms were the most constant, and varied from a slight weakness of the muscles of the lower extremities to a complete paralysis of the latter and also those of the trunk and upper extremities. This paralysis persisted, as a rule, longer than the local disturbances of sensation, lasting in some instances almost two days. The reflexes were first diminished, then abolished, and then returned slowly; retention of urine was almost always present. Great variability was also noted in the effect on the mental faculties; total unconsciousness was present in only six cases, and when the patients came out of the resulting coma they were restless and showed unmistakable evidences of mental confusion. The respirations were always markedly inhibited and thus served as an indication of approach to the danger line. Vomiting was present in all the cases in which the magnesium sulphate had produced any marked effects, and sometimes was annoying and persistent.

It is quite apparent that the effects of this drug as an anesthetic are so variable that some hesitancy must govern any recommendation for its general use, even if spinal anesthesia were as desirable as general anesthesia by the usual methods. Blake points out several features in its favor which are not possessed by cocaine, chief among which is the absence of any depressing action on the heart. Its action is also more general, but in the full doses thus required it is difficult to gauge the effect, and alarming results may follow. The prolonged action which has been noted may make its use desirable when a prolonged anesthetic effect is needed, such as in the treatment of aneurysms by compression, and its marked effect on the perineum may be of some value in doing a prostatectomy on a patient with bad kidneys and a myocarditis. In view of the associated dangers and uncertainties, however, it is doubtful whether any extended application will ever be accorded to this procedure.

Blake also had an opportunity of studying the effect of magnesium sulphate injections in cases of tetanus, where its use was suggested by the marked inhibition which had been noted on both afferent and efferent nerve impulses. It was given in connection with other antitetanic measures, and in one of the two cases in which it was employed the results were apparently favorable. The other was practically a hopeless case, but even here a marked effect in restraining the convulsions was noted and the pain was relieved. As the spasm of the muscles of mastication and deglutition was lessened, feeding was more easily accomplished. The effect of the substance was continued over considerable periods, from twenty-nine to thirty-seven hours, without any cardiac depression; the repeated injections seemed to have no harmful effect, but a certain degree of tolerance became established. As to what the action of magnesium sulphate may be in tetanus, we are still in the dark. Although it may have some chemical action on the toxins, Blake thinks that its effect is purely symptomatic, and it may therefore be employed with perfect justification as an adjuvant to other treatment, mainly the use of antitoxin.

SUBCUTANEOUS INJECTION OF FATS.

THE necessity of supplying the organism with nutriment in cases in which its administration by the normal channels cannot be conducted either completely or partially has led to the introduction of a number of methods for overcoming this difficulty. Among these rectal feeding has, perhaps, found the greatest vogue; but this has its limitations, and the attention of the clinician and therapeutists has therefore been directed to other channels. The subcutaneous administration of fat was suggested as a means of supplying the body with nutriment for a time, but animal experiments showed that fat was unsuitable for this purpose, and the observations of Winternitz proved that but two or three grams of this material was absorbed daily when five hundred grams had been injected during a period of five days in the human subject. The fat injected in this case contained iodine in combination which was set free dur-

ing the process of oxidation so that the amount excreted in the urine could be readily determined, and an estimate was then made of the quantity of fat absorbed. The method is still used, however, to a limited extent as an emergency measure, for it is claimed that part of the absorbed fat escapes oxidation and becomes stored in the tissues and replaces the fat which has been used up in the body.

This theory has now been put to a further test by Winternitz, and the results of his new experiments have been recently published in the *Therapie der Gegenwart* for June, 1906. A certain number of dogs received subcutaneous injections of fat containing a definitely known quantity of iodine, and were also fed freely in the usual manner. An equal number received the same quantity of fat subcutaneously but otherwise were fed very sparingly. The animals were killed eight days after the last injection, and in those which had been freely fed the iodized fat could be readily demonstrated in the adipose tissues of the liver, the bone marrow, the mesentery, the heart, and the kidneys, but in the poorly fed subjects none of the organs and tissues mentioned contained any traces of the same. This seems to show that in the well-fed animals a part of the absorbed fat was deposited in the adipose tissues, and that in the others it was used up or oxidized. If the fat is absorbed to only a limited degree then the amount of iodine in the blood must also be necessarily small; and this was found to be the case in observations conducted for the purpose. Now, the fat undoubtedly disappears within a few hours from the site of injection in these starved animals, and the question will naturally be asked, Where does it go? Winternitz claims that it is simply present as a foreign body in the tissue spaces, and in this way spreads itself over a large area of the body; but it

o absorption in the accepted
lymphatic spaces represent
es, and the fat globules must
helium or else reach the cir-
would mean that absorption
very slowly, for the favorable

conditions present in the intestine do not hold here. Believing that if the fat were given subcutaneously in the form of an emulsion it would more closely simulate the natural conditions, Winternitz made such a preparation combined with a pancreatic ferment. But these attempts also resulted in failure, for not only was the degree of absorption even less, but, in spite of all precautions, the danger of infection was always imminent here as in the other cases.

The unfavorable results obtained by this observer would warrant the conclusion that the value of subcutaneous feeding is very questionable, and that, in view of the dangers and uncertainties of the procedure, it had, perhaps, better be given up and relegated to the scrap heap of abandoned therapeutic suggestions.

"TELEPHONE TERRORS."

Among the so-called modern improvements there is none which has gained more rapidly in general use than the telephone. Of its importance and advantage there can be no question, and now that the labors of the electrical engineer have resulted in the production of a fairly perfect instrument and service, there are certain undeveloped features in connection with its use which call for advice and study by his sanitary confrère. It must unfortunately be admitted that as regards the public telephones but little attention has thus far been paid to the sanitation of either the instrument or its surroundings. In many places a booth of some sort is provided to insure privacy, but as noted in a recent article with the above title in the *Municipal Journal and Engineer* (Vol. XXI, No. 3), there is little attempt made either to ventilate or to clean it. When not in use the door is invariably closed, so that whatever emanations may have been given forth by the last occupant are not permitted to escape, and its construction is of such a type that it can be kept clean only with difficulty. Then of perhaps greater importance is the condition of the mouthpiece of the instrument, which serves as a very efficient catch-basin for a variety of undesirable products. It has been conclusively demonstrated that during speech minute particles of saliva are expelled, which contain in many cases germs of various kinds, in consequence of which surgeons have been accustomed to wear some sort of guard over the mouth and to indulge in as little conversation as possible during the course of an operation. One can readily imagine what a collection of material is deposited during the course of the day into the mouthpiece of even a moderately used public telephone instrument.

Improvements are certainly indicated, and as our health authorities can exercise their power in reference to cleanliness of other public utilities, there seems no good reason why it should not be extended to the telephone system. It would be a simple matter, for example, to require that the door of a booth be kept open by means of some suitable contrivance when the 'phone is not in use, in order that it may at least be aired. An attachment could also be devised for the instrument by which the mouthpiece could be rendered a source of less danger. Surely the ingenuity with which the American is usually credited can be exercised to devise some means, effective and yet inexpensive, by which the desired result may be accomplished. It may be necessary, however, that the public mind be aroused by newspaper comment and otherwise before the matter is taken up by the proper authorities and called to the attention of the telephone companies.

Thyroid Migraine.

Migraine is apparently one of those conditions for the relief of which therapeutic suggestions never seem to decrease either in number or variety, and the prevalence of the complaint furnishes plenty of material for their trial—and subsequent abandonment in many cases. The disturbance itself probably depends on a variety of causes other than eyestrain, and it is useless to apply remedies without a careful study of the particular case in hand, an omission, unfortunately, only too prevalent. Among numerous etiological factors disturbances of the thyroid gland appear in certain instances to play an important part, as demonstrated by careful observations made among others by Levi and Rothschild (*Wiener klinische Wochenschrift*, No. 28, 1906), who report a series of cases in which treatment with thyroid extract was followed by well-marked improvement in the pa-

tients' symptoms. In all of these cases there were phenomena present which corresponded with the clinical picture of a chronic hypothyroidism of a benign type, including metrorrhagia, fatigue, chilly sensations, loss of appetite, pains in the joints, constipation, and trophic disturbances of the nails and hair. The relation between migraine and the thyroid may also become evident during pregnancy, when an increased functional activity in this organ, so frequently noted, is accompanied by a complete disappearance of the "sick headaches" previously complained of by the patient. The appearance of migraine at the time of puberty and its spontaneous disappearance during the climacteric may also be looked upon as bearing some relation to certain physiological changes in the thyroid gland coincident with these periods. The apparent proof of this connection seems to be shown, however, in the benefit derived from thyroid treatment, which, as already noted, has been followed by relief from pain. At any rate the suggestion that the remedy be tried in cases of migraine of undetermined origin is worthy of trial.

Albuminuria Following Kidney Palpation.

A number of years ago the interesting observation was made by Menge that albumin frequently appeared in the urine of patients who were the subjects of renal ptosis after these organs had been examined by palpation. Schreiber (*Zeitschrift für klinische Medizin,* Vol. 55, No. 3) has made some further investigations along these lines, and as a result of his observations concludes that this albuminuria is a constant phenomenon in these cases; indeed, he was able to demonstrate it with absolute certainty in thirty-nine out of forty-two patients examined. The albumin was found in the urine within ten or fifteen minutes after palpation was begun, and disappeared usually within the same length of time, although sometimes it persisted for two hours. In those specimens which were examined microscopically there were found, in addition, renal epithelium and red and white cells, but no casts. Schreiber believes that the albumin appears in the urine because the blood serum is forced directly through the walls of the capillaries by the pressure of the examining hand. When contraction of the abdominal muscles interferes with proper palpation the phenomenon in question cannot be elicited, but when palpation can be effected an albuminuria will result, even when only one pole of the kidney is compressed. In cases in which this condition persists beyond the day of the examination, it must be assumed that the kidney is acutally diseased. Schreiber thinks this phenomenon may be made use of in the differential diagnosis of certain abdominal conditions. Thus, if there is some doubt whether a certain area of resistance encountered during an abdominal palpation is due to the liver, gall-bladder, spleen, or kidney, the appearance of an albuminuria such as that described will point to the kidney as the source of the same.

Trauma and Diabetes.

Although long a matter of conjecture, the actual etiological connection between trauma and diabetes or glycosuria has never been fully cleared up, notwithstanding the numerous experimental studies which have been devoted to this subject. From a closer examination of the literature, and as a result of his personal observations, Kausch (*Zeitschrift für klinische Medizin,* Vol. 55, No. 3) believes that we may group these cases in four classes, depending on the severity of the glycosuria, as follows: (1) True chronic diabetes; (2) curable diabetes or glycosuria; (3) ephemeral or spontaneous, and (4) alimentary glycosuria. Kausch found that a true diabetes is often reported after head injuries, particularly of the occipital region, but doubts whether this is actually produced by trauma, as no definite proof has ever been brought forward of such connection. True diabetes can never be cured; it merely, according to Kausch, remains latent for a time. A "cure" exists only when the patient is able to ingest large amounts of carbohydrates, sugar excepted, without producing a glycosuria. Opposed to the noncurable is the transitory form of diabetes, or, more properly speaking, glycosuria, in which the amount of sugar is not great, but the polyuria is marked. This type may follow a trauma, and, like the ephemeral variety, persists for only a few days. But in the latter there is no polyuria, and the quantity of sugar is also small. An alimentary glycosuria was noted in several cases after trauma, the maximum amount of sugar being 0.43 per cent. These forms of transitory glycosuria have usually been noted after injuries to the skull; but whether they are due to the shock, to the psychic effect, or to mechanical causes, it is impossible to determine from the data at hand.

The Pathogenesis of Icterus.

Formerly it was universally taught that jaundice was invariably due to mechanical obstruction somewhere along the course of the biliary passages, until the discovery was made that in addition to the hepatogenous there was also a hematogenous variety of icterns. The latter was found to be due to the disintegration of large numbers of red blood cells in the vessels. But as the change of the blood pigment into bile pigment undoubtedly takes place within the liver itself, this distinction was again abandoned. Minkowski, writing in the *Zeitschrift für klinische Medizin,* Vol. 55, No. 3, has recently suggested that icterus may also be due to a functional disturbance in the secretory processes residing in the hepatic cells, by which the direction of the stream is changed and the bile finds its way directly into the circulation from the liver cells instead of being guided into the hepatic ducts. Eppinger has also claimed as the result of his microscopical investigations that icterus may result from a stasis in the bile capillaries, resulting in a rupture of the latter and the entrance of the bile into the lymphatics and from these into the blood. Minkowski believes that although this variety may exist, an icterus by "parapedesis" is also possible.

News of the Week.

Meeting of the American Medical Association.—The date set for the meeting of the A. M. A. at Atlantic City is June 4, 5, 6, and 7, 1907. An endeavor was made to arrange dates with the executives of the Congress of Physicians and Surgeons, so that the meeting of one body should immediately follow that of the other, but this was found to be impracticable.

Behring's Tuberculosis Remedy.—True to his promise made to the International Congress on Tuberculosis in Paris last autumn, Behring announces that the new remedy is ready for delivery in small quantities to clinicians who are in posi-

tion to make satisfactory tests. He is not ready to put the remedy on the market, as it has not yet been sufficiently tested, but hospital physicians will receive it in small amounts free of charge. The remedy, which is called tulase, may be given hypodermically or per os.

Transfer of Quarantine Stations.—The South Carolina quarantine stations have been transferred to the general government, and will in future be under the control of the U. S. Public Health and Marine Hospital Service. The transfers are in the form of leases for five years at the nominal rate of five dollars per annum.

A Naval Medical Officer Dismissed.—An assistant surgeon of the navy who was recently tried by courtmartial on the charge of cribbing while undergoing an examination for promotion, has been sentenced to dismissal from the service. The court found him guilty of conduct unbecoming an officer and a gentleman in that during the examination he communicated with a fellow officer and obtained assistance from him in answering questions. The man from whom the accused asked and obtained information was also tried and sentenced to a loss of fifteen numbers in rank.

The Dedication of the Harvard Medical School will take place, it is announced, on September 26. President Eliot will make the dedicatory speech, and addresses on behalf of the departments of anatomy, surgery, and internal medicine will be made by Drs. Dwight, Warren, and Shattuck. The addresses will be limited to ten minutes each, and none of the rich men who have built the school will be allowed to say a word.

The Brooklyn Hospital for Contagious Diseases.—Many residents of Brooklyn have joined in a protest against the continuance of the hospital for the treatment of contagious diseases on Kingston Avenue. The Board of Health has made application for an appropriation of $325,000 for certain repairs and the erection of a diphtheria pavilion, and those who ask for the removal of the hospital will oppose the grant when the matter comes up for consideration before the Board of Estimate and Apportionment next month. It has been suggested that the hospital be removed to Barren Island.

Establishment of Tuberculosis Camp at Dunning (Illinois).—The Chicago Tuberculosis Institute was recently granted the privilege of establishing a camp for the benefit of consumptives in the grounds of the Cook County Institutions, at Dunning, Ill. This camp, it is said, will be kept open until November 1, and the first inmates will be twenty female patients. The attending staff consists of Drs. Henry B. Favill, Ethan A. Gray, and Theodore Sachs.

Iowa State Hospital for Tuberculosis.—At the recent meeting of the Iowa State Legislature an appropriation of $50,000 was made for the purchase of a site for the proposed State Tuberculosis Hospital. The Board of Control has selected a tract on the high ridge separating the valleys of Beaver Creek and the Des Moines River; this is the highest point in that part of the State, and from it a view is had in any direction over from ten to twenty miles of country.

A Tuberculosis Ward for a Public Hospital.—It is proposed to build a special open-air ward for the treatment of the tuberculous patients in the Douglas County, Neb. (Omaha) Hospital. The ward will be constructed by adding an extension to the west portion of the hospital.

A New Hospital for Tuberculosis in Staten Island.—Plans have been filed with the Building Department for the new tuberculosis hospital which it is proposed to erect in Richmond borough on land purchased not long ago near the present City Farm. The hospital is to be known as Sea View Hospital. The buildings will be eight in number, each four stories in height, and about 80 feet by 137 on the ground plan.

A Southern California Health Camp.—Sufficient money is now available to provide for the purchase of the tract desired for the Health Camp which it is proposed to establish near Pasadena, on the road to Linda Vista, and also for the erection of the central building, in which will be located the offices, dining room, and reception rooms.

Large Bequests to Charities.—According to the will of Isaac Glazier, who died in Germany in June of the present year, $2,500 each is given to the Mount Sinai Hospital, the Hebrew Technical Institute, the Montefiore Home for Chronic Invalids, the Hebrew Benevolent and Orphan Society, the Home for Aged and Infirm Hebrews, and the Hebrew Educational Alliance. The will also directs that $25,000 be devoted to charitable and benevolent institutions besides, of which $15,000 will go to institutions in San Francisco, and $5,000 to institutions in Frankfort-on-the-Main, Germany.

The Ear as an Index of Character.—A despatch to *The Sun* says that, at the Congress of German Anthropologists, recently held at Görlitz, Prof. Blau read a paper on the formation of the ears of criminals and lunatics. He had taken accurate measurements of 1,061 ears, of which 255 belonged to lunatics and 343 to criminals, and concluded that in a vast majority of cases the external ear is larger in criminals and lunatics than in normal persons. This is especially noticeable in the helix and in the lobe. The larger the helix is the lower is the state of mental development. Abnormal development of the helix is especially noticeable among criminals charged with sexual crimes.

An Epidemic of Rabies in Lisbon.—The London *Express* says that there was a remarkable prevalence of hydrophobia in the capital of Portugal at the beginning of this month. Within less than a week 123 mad dogs and cats were killed in the streets, and many persons were bitten and treated at the Pasteur Institute. A party of German tourists landed at Lisbon recently from an excursion steamer. Several members of the party were bitten by a mad dog before they had been in the city two hours and were taken immediately to the Institute.

Yellow Fever.—Dr. C. H. Irion of the Louisiana Board of Health announced on Sunday of this week that a case of undoubted yellow fever had been discovered at New Iberia in the person of a mulatto boy, twelve years old. The boy was living in a sparsely settled portion of the town, and it is not known how the case originated. There have recently been two cases reported in Havana and one in Matanzas, and at Santiago de Cuba one Sister of Charity has died and another is ill with a disease suspected to be yellow fever.

Reform Necessary in the Illinois Insane Asylums.—In its quarterly bulletin, recently issued, the Illinois State Board of Charities announces a reform in the management of the State Asylums for the Insane. The bulletin says that the Board

found the hospitals for the insane topheavy on the custodial side. "The superintendents are burdened with business details that prevent them from giving sufficient attention to medical administration. The hospitals are more like great detention boarding houses than places for the modern treatment of hopeful cases and the industrial reeducation of chronic types."

The American Academy of Ophthalmology and Otolaryngology.—The eleventh annual meeting of this association will be held at the Hotel Oakland, St. Clair, Mich., August 30, 31, and September 1, 1906. St. Clair is on the St. Clair River, fifty miles north of Detroit. Any member who wishes to show clinical cases or make a demonstration of instruments, or who wishes to show any collection, is requested to communicate with Dr. Louis J. Goux, Stevens Building, Detroit. The secretary of the Academy is Dr. George F. Suker, 100 State Street, Chicago.

The International Medical Association of Mexico will hold its second annual meeting in the City of Mexico November 14 to 17, under the presidency of Dr. R. D. Robinson of Torreon. Members of the profession in the United States and Canada are cordially invited to be present. All the papers and the discussion will be in English. The secretary is Dr. W. R. Jamieson, Torreon, Coah.

A New Medical Society in Virginia.—The physicians of Brunswick and Mecklenburg counties, Virginia, met at La Crosse on August 14 and organized a new medical society. Officers were elected as follows: *President,* Dr. W. W. Wilkinson of La Crosse; *Vice-Presidents,* Drs. Hunter Marrow of Union Level and Herbert Lewis of Lawrenceville; *Secretary,* Dr. S. T. Jett of South Hill; *Treasurer,* Dr. B. T. Montgomery of Red Lawn.

A New Medical Society in Quebec.—The physicians of Nicolet County, Quebec, have founded a county medical society, the following officers being elected for the first year: *President,* Dr. H. Veilleux, Ste. Gertrude; *Vice-President,* Dr. Trudel, St. Gregoire; *Treasurer,* Dr. P. V. Landry, Becancour; *Secretary,* Dr. L. S. Giroux, Gentilly.

The Augusta County (Va.) Medical Society.—At the annual meeting of this society, held August 8, the following officers were elected: *President,* Dr. J. W. Freed; *Vice-Presidents,* Drs. Alexander, Whitmore, and Roller; *Treasurer,* Dr. T. M. Parkins; *Secretary,* Dr. M. J. Payne.

Dr. C. S. Millet of Brockton has been appointed secretary of the newly-established Massachusetts State Tuberculosis Commission.

Obituary Notes.—Dr. M. L. Greenfield of Rockland, Mass., died suddenly on August 9. He was born in Orwell, N. Y., forty-seven years ago, and was graduated from the New York University Medical School in 1884. He practised for twenty years in Verona, N. Y., and removed to Rockland in October, 1905.

Dr. William Edwin Taylor died in Honolulu on August 30, at the age of sixty-nine years. He was born in Virginia and entered the medical corps of the Navy in 1859. He was retired for ill health in 1881 with the rank of Medical Inspector. For eighteen months he was professor of surgery in the University of California, and for a portion of that period was president of the San Francisco Medical Society. He went to Honolulu to live in 1898. There he served at various times as president of the Hawaii Medical Society and as a member of the Board of Medical Examiners and the Board of Dental Examiners of the Territory.

Dr. S. S. Meadon died on August 6, at his home near Hartsville, Tenn., at the age of eighty-two years. He served as surgeon in the Confederate Army, and at the close of the war resumed the practice of medicine in Nashville and later in Gallatin. He retired to his country home a few years ago.

Dr. H. D. Harris of Jackson, Tenn., died on August 7, after an illness of one week. He was graduated from the Muttshaus Medical School in 1861 and served in the medical corps of the Confederate Army throughout the war, where he distinguished himself on numerous occasions for his bravery and devotion to the cause of the sick and wounded under his care.

Dr. Frederick A. Roberts of Wilmington, Mass., died on August 11, following an operation for appendicitis. He was born in Waterboro, Me., in 1873, and was graduated from the Medico-Chirurgical College of Philadelphia in 1901.

Dr. Daniel Ellison of Ashland, Va., was drowned on August 12, while fording a swollen stream on his way to visit a patient. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1879.

Dr. Henry Austin Gould died at Minneapolis on August 7, aged, eighty-three years. He was born in Norridgewick, Me., and began his working life as a machinist. In 1868 he became a Congregational minister in Wisconsin, but soon took up the study of medicine and was admitted to practise in 1874. In 1885 he retired.

Dr. Charles Albert Cochrane of Augusta, Me., died August 13, at the age of seventy-three years. He was born in Monmouth and was graduated from the Medical School of Bowdoin College in 1856.

Dr. J. W. Elliott of Deposit, N. Y., died August 9, after an illness of over two years' duration, at the age of seventy-one years. He had been in practice nearly fifty years.

Dr. J. W. Ferguson of Shawhan, Ky., died August 10, at the age of fifty years. He was born in Williamstown, Ky., and was a graduate of the Medical Department of the University of Louisville in the class of 1889.

Dr. Charles D. Hunt of Atlanta, Ga., died August 12, at the age of sixty-three years. He was born in Russell County, Ala., July 26, 1843, and was graduated from the Medical Department of the University of Georgia in the class of 1871. He had practised in Atlanta since 1892.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE SCIENTIFIC CONGRESSS PRESIDENT'S ADDRESS — HYDATIDIFORM MOLES—THE LATE MR. BEIT'S LEGACY—ROYAL CHARTER SOUGHT BY SUNDAY HOSPITAL FUND.

London, August 3, 1906.

The British Association for the Advancement of Science is holding its seventy-sixth annual meeting at York, in which city it met twenty-five years ago and in which it took its origin fifty years earlier. The new President is Professor Ray Lankester, who delivered his address on Wednesday, taking as his subject the progress of science during the twenty-five years since the previous York meeting. He declared that, exciting and of entrancing interest as are some of the discoveries, there has been nothing to indicate that we are on a wrong path—nothing that cannot be accepted by an intelligent modification of previous conceptions. Though some onlookers have told the public that science is at an end, others have asserted that the new discoveries are inconsistent with the foundations of knowledge and justify every absurdity of unrestrained fancy. These two mutually destructive accusations are due to ignorance or traditions of self-interest, and one object of the Association

is to show that science has not come to the end of her work, but has only given a foretaste of what is in store for mankind.

The President then passed on to consider the developments of chemistry, referring to the discovery of five inert gaseous elements by Rayleigh and Ramsay, and then to the finding of radium by the successive efforts of Henri Becquerel and M. and Mme. Curie. "There can be no doubt," he said, "that the past quarter of a century will stand out forever in human history as that in which new chemical elements, not of an ordinary type, but possessed of truly astounding properties, were made known with extraordinary rapidity and sureness of demonstration." Of these he dwelt on radioactivity as the discovery surpassing all others in respect of the novelty of the properties of matter so suddenly revealed. A new conception of the structure of matter, he pointed out, was necessitated by it, and yet so far from being disconcerting, this new conception, he held, fits in with and justifies older schemes. He then passed in review some of the most marvelous facts and deductions necessitated by the discovery, including the work that has been done as to the nature and possible transformation of atoms and the speculations on astral chemistry. Turning from radium, the president discoursed on electricity, chemistry, and astronomy, and closed this section with the remark: "And yet M. Brunettière and his friends wish us to believe that science is bankrupt and has no new things in store for humanity!" Coming to physiology, the professor referred to the discovery of the continuity of protoplasm through the walls of the vegetable cell as a most startling fact in connection with plant structure. He is inclined to agree with those who hold that the simplest form of life at present existing is a highly complicated structure—a nucleated cell, though that does not imply that simpler forms of living matter have not preceded those we know. But improved methods and increased knowledge have made an end of the arguments for abiogenesis.

I must pass from these and other interesting subjects to what the president had to say on disease and hygiene. He condemned energetically the parsimony which assigns paltry sums—a mere nothing, a few thousands—to investigations having for object the destruction of disease, while the people are dying by thousands of preventable diseases. He deeply regretted that there was no general desire to bring the advances of science to bear on the welfare of the community. "If the people of Britain wish to make an end of infective and other diseases they must take every possible means to discover capable investigators and employ them for this purpose."

In conclusion the president said: "It seems to me not inappropriate that a society for the advancement of science should have taken its origin under the walls of Yorkminster and that the clergy of the great cathedral should have stood by its cradle. It is not true that there is an essential antagonism between the scientific spirit and what is called the religious sentiment. 'Religion,' said Bishop Creighton, 'means knowledge of our destiny and of the means of fulfilling it.' We can say no more and no less of science. Men of science seek, in all reverence, to discover the Almighty, the Everlasting. They claim sympathy and friendship with those who, like themselves, have turned away from the more material struggles of human life and have set their hearts and minds on the knowledge of the Eternal."

Dr. James Oliver has communicated to the Gynecological Society a study of hydatidiform mole with records of three cases. He holds there is no such thing as a decidua reflexa. With regard to menstruation, he did not believe in the denudation theory. Retention from imperforate hymen was against it. Hydatidiform mole was degeneration of the varicose surface of the chorion, many of its processes becoming converted into cystlike bodies. It was independent of uterine influence, solely due to an aberration of the germ plasm. This aberrant product can develop in a uterus concurrently with a normal one; *i.e.* two germinal elements have been fertilized, one taking an abnormal, the other a normal course. The change which produces a vesicular mole begins at an early stage, between the third and sixth weeks, while the allantois is active, before differentiation in the chorionic villi; hence it rarely happens that a semblance of an embryo is to be found in the débris. A mole may occur in a woman who has had healthy children or in one who has never been pregnant. Among the symptoms pain is often complained of, but seldom until the hemorrhagic discharge attracts attention. In the early days there may seem to be only pregnancy; later we are confronted with intrauterine death. The diagnosis was considered by Dr. Oliver and his three cases described.

Dr. Macnaughton Jones communicated a case and advocated curettage after every suspicious mole. Dr. Heywood Smith thought in that case the curettage was justifiable, as he did not think the specimen possessed the characteristics of hydatidiform mole. He suggested that the regeneration of villi began earlier than Dr. Oliver had stated. Dr. Aarons asked about the subsequent history. Different opinions were expressed by other speakers as to pain, and one held that it had not been proved that conception was necessary for the production of moles.

In replying to the several views put forward, Dr. Oliver said he did not think it possible for change in the villi to take place before the third week. No doubt the condition was inherent in the oosperm as soon as the coalescence of spermatozoon and ovum occurred. There was a tendency to produce a mole, but it could not be selected until the ovum was placental. As natural conception might occur later, he did not advocate curettage. According to the pathology of chorionic epithelioma, moles seem to have a tendency to imbed themselves in the uterus, and it was a question whether mere curettage would prevent cases becoming malignant later. He could not explain pain. It was the same as in other conditions. He did not think it due to an attempt of the uterus to expel the mole. He believed all moles were alike; microscopically they did not differ. He did not think it possible for a hydatidiform mole to occur in a woman who had not had sexual intercourse. The mole was unquestionably due to the fertilization of the germ plasm.

The late Mr. Beit bequeathed £25,000 to the proposed Institute of the Medical Sciences in connection with the London University, £20,000 to Guy's Hospital, a like sum to King Edward's Hospital Fund for London, and another sum of £20,000 to his trustees to distribute among London charitable institutions.

The Hospital Sunday Fund has submitted a petition for the grant of a royal charter. Any petition against it must be lodged at the Privy Council office before September 3.

OUR PARIS LETTER.

(From Our Special Correspondent.)

MALARIA IN MADAGASCAR—ROENTGEN RAYS FOR GRAY HAIR—RADIOTHERAPY OF CANCER—SUTURE OF THE HEART—DEATH OF PROF. BROUARDEL.

PARIS, July 30, 1906.

At a recent meeting of the Academy of Medicine an interesting discussion took place regarding malaria in Madagascar. Professor Blanchard cited statistics to prove the progressive increase of this disease in the island, especially in the larger cities, as in Tananarivo, for example—a city which was nevertheless reported to be the least insanitary of all in Madagascar. The present epidemic, of wide extent and very fatal, was due indirectly to the great works of public utility which had been carried out, especially to the building of the railroad between Tamatava and Tananarivo. The laborers engaged in these works, suffering from malaria, carry the infection with them from one part to another, the development of the disease being also favored by the excessive humidity of the climate. Two varieties of mosquito, *Myzomyia funesta* and *Pysctophorus costalis*, seem to be the agents for the transmission of the hematozoan parasite, most to be feared in Madagascar. The habitat of these mosquitos is being gradually extended so as to include even the elevated tablelands, which are thus losing their reputation for salubrity. Up to the present the only measures taken have been to facilitate the use of quinine by the malarial sufferers, but this seems to have been insufficient in restricting the epidemic, and the author proposed that the Academy should adopt resolutions calling for the institution of more effective prophylactic measures. M. Kermorgant said that the Government, in its efforts to suppress the epidemic, had ordered the draining of the marshes, the cutting down and burning of brushwood, the circulation of pamphlets of instruction, the free distribution of quinine, etc. But, despite all these measures, there was always a marked recrudescence of malaria in the rainy season—a phenomenon observed in Tonquin and the island of Réunion, as well as in Madagascar. One of the most efficacious measures was thorough screening of doors and windows, but it was difficult to apply this universally. Professor Laveran said the principal product of Madagascar was rice and the cultivation of this necessitated swamps, the drying up of which would simply substitute starvation for malaria. To this Blanchard replied that it was not proposed to dry up the rice fields, but only to fill up the pools around the houses and other artificial collections of water. The work of the Americans in Cuba had consisted in filling up the puddles and in removing tin cans and other hollow objects in which rain water collected. Those measures had been eminently successful in reducing the number of mosquitos. On the other hand, in Italy, where the peasants live in cabins the authorities had adopted the plan of screening doors and windows, with perfect success. At the close of the discussion the Academy adopted a resolution calling for

the appointment of a commission at Tananarivo to investigate the causes of the increase of malaria in the island and to determine upon the best measures for combating the spread of the infection.

An interesting and original communication on the pigmentation of hair by *x*-rays was presented to the Academy of Sciences by MM. Quibert and Marquès. These authors had observed that the hair of the scalp and beard became markedly pigmented when exposed to the prolonged action of the *x*-rays, and this pigmentation appeared to be lasting. Even perfectly gray hair was darkened by the *x*-rays and the color so produced had remained unchanged for months. The change was not necessarily preceded by a falling of the hair.

M. Barbario recently reported to the Society of Hospital Internes a case of recurrent alveolotubular carcinoma of the breast completely cured in two months by exposure to the Roentgen rays combined with the internal administration of magnesium chlorate.

Two cases of suture of the heart were reported to the Surgical Society by M. Rochard. The operation was performed in each instance by Lenormant. Commenting on the cases, the speaker said that in syncope occurring under anesthesia one should, as a matter of last resort and when artificial respiration, tongue traction, etc., had been tried without avail, employ massage of the heart. The author favored the subdiaphragmatic method of approach to the heart, for in syncope the diaphragm is always relaxed, which renders it possible to seize the ventricular portion of the heart and so to massage the organ in spite of the intervention of this muscular partition. Of five recorded cases this measure had been definitely successful in three. M. Manclaire would try the subdiaphragmatic method first, but if this was unsuccessful he would divide the diaphragm and seize the heart directly, for in so doing one could better aid the coronary circulation.

A great medical figure has disappeared in the person of Professor Paul Brouardel, who died from an incurable malady in the course of a few weeks. He was born in 1837 at Saint-Quentin and obtained his degree in 1865. In 1869 he was appointed professeur agrégé at the Faculté de Paris, and was nominated full professor of legal medicine in 1879. He was elected a member of the Academy of Medicine in 1881 and in the same year was made dean of the medical faculty of the University of Paris. In 1892 he became a member of the Institute. He was a grand officer of the Legion of Honor and was the possessor of many foreign orders conferred upon him when filling important scientific missions as the official representative of France. Brouardel was one of the first great scientists devoted to the subject of municipal hygiene, and he did much to demonstrate the importance of this science in a sociological sense. He devoted much of his life to the combat against tuberculosis, and early in his career he had preached the doctrine of the spread of typhoid fever by means of a contaminated water supply. In legal medicine Brouardel leaves a name universally respected. He was director of the laboratory of the morgue of which he made with his practical spirit and his scientific attainments a model teaching institute. He won for medical jurisprudence the respect of all in demonstrating its value as an aid to the administration of justice. The value of the services rendered by him to his country will keep the name of Brouardel ever in remembrance. His death is a grievous loss to French medicine.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

INTESTINAL MYIASIS—PREVENTION OF VENEREAL DISEASES—LYSOL POISONING—SPEECH PERCEPTION—THE CHARITÉ HOSPITAL—HYPEREMIA IN TUBERCULOSIS—THE VIRCHOW MONUMENT.

BERLIN, July 4, 1906.

A PAPER on intestinal myiasis read by Wirsing before the Society for Internal Medicine was of great practical interest. The speaker said that the larvæ of three kinds of diptera were found in animals, causing cutaneous myiasis due to the *Dasselfliege*, myiasis of the pharynx in sheep caused by the *Œstrus*, and intestinal myiasis in horses caused by the *Gastrophylus duodenalis*. The occurrence of human myiasis was very rare, though Schlesinger had quoted somewhat over a hundred cases. Wirsing had seen three cases caused by the common fly; in one of these the infection had taken place per anum, and among the symptoms produced were restlessness, diarrhea, intestinal cramps, and attacks of hallucination. Danger arose through erosion of the intestinal wall, hemorrhage, and inanition. Good results followed the use of purgatives, especially calomel and the bitter mineral waters, and the various anthelmintics.

At the last session of the Berlin branch of the German Association for the Prevention of Venereal Diseases, Oppenheim read a paper intended especially for the instruction of the laity. He said that the nervous system of the modern man was very irritable, as a result of the civilization of to-day. Gonorrhea sometimes though but rarely gave rise to diseases of the nervous system, such as meningitis or neuritis, causing disorders of gait similar to those of tabes. Syphilis, on the other hand, was responsible for many nervous affections. Raymond of Paris was right in saying that without syphilis and alcohol the specialists in nervous diseases would lose their occupation. In order to illustrate the fact that iodine and mercury are very effectual in many cases, but not so in others, the speaker compared syphilis to a fire breaking out in a building adjoining a palace, this palace being the nervous system. In case the drugs mentioned were effective, the palace was protected by plenty of water, but if this were not so the palace might be regarded as containing great quantities of explosives which were reached by the fire and destroyed the edifice. The fire caused the explosion, but the destruction was due to the explosive substances. Syphilitic diseases of the nervous system were to be avoided by early treatment and strict obedience to the medical adviser.

Much discussion followed the reading of a paper before the Society for Internal Medicine by Blumenthal, on lysol poisoning. Lysol, he said, was a solution of cresols in soap and acted as a corrosive poison, with a particular affinity for the nervous system. It was but slowly absorbed and rarely gave rise to vomiting; the blood was not affected and showed no morphological alterations. The muscles, brain, and lungs contained about the same amount of the cresols, the liver holding most of it. In investigations on dogs the author had found that fatty tissues contained even more than the liver, and he concluded that the lipoid tissues dissolved such bodies and served to bring the poison into contact with the body cells. Lysol poisoning was usually recovered from in three or four days, without permanent damage. The treatment recommended consisted in washing the stomach with milk, and intramuscular injections of digitalis. In the discussion Burghard pointed out that very serious cases also occurred, with symptoms of great gravity, lasting for weeks and even ending fatally. He had used magnesia and subnitrate of bismuth with good results in the treatment. Westenhoeffer had observed tracheitis, bronchitis, and pneumonia, Mosse and Hirschfelt, nephritis as the result of poisoning with this agent, and Plehn stated that in fifty cases he had seen pneumonia but once and only one patient had died.

A paper on a subject rarely discussed in medical circles was read by Gutzmann before the same society, on the limits of the perception of speech. Speech, he said, was perceived by hearing, feeling, and sight; these senses being highly cultivated by man. In order to investigate this subject he had studied the powers of perception for long series of disconnected syllables. In dictating indoors 111 words devoid of sense with 233 syllables, twenty-six mistakes were noted, and on repeating the experiment in the open air it was found that the number of errors was increased and that the person under observation exhibited less acuity of hearing. For the perception of speech by sight the movements of the lower jaw, lips, cheeks, and the roof of the mouth came into consideration. Of great importance for the recognition of sounds was the knowledge of the words most often used; the three German words *die, der, und* comprised nearly 10 per cent. of ordinary speech, and sixty-six words comprised nearly 50 per cent.

Two departments of the renovated Charité Hospital have been recently opened. On June 10 the formal exercises were held in the old building, which has become celebrated through Virchow's work. The new pathological building was inspected by the guests and an address of dedication was delivered by Prof. Orth. On June 11 the new Dermatological Hospital was opened by Lesser, who in his address pointed out the great development of this branch of medicine and especially commented on the significance of the discovery of the *Spirochæta pallida* as the causative agent of syphilis. Beautiful demonstrations of the organism were exhibited by Hoffmann.

At the third convention of the German Society of Tuberculosis Physician Kuhn demonstrated a method for curing early tuberculosis by hyperemization by means of his aspirating mask. He stated that an important reason for the frequent localization of the disease in the pulmonary apex was to be found in the anemia due to imperfect respiration. He had designed a mask which was intended to prevent breathing through the nose and thereby produced hyperemia of the lungs by congestion. Inspiration was made more difficult and was therefore prolonged, but expiration was free, and the congestion accompanying the use of the mask could be demonstrated with the Roentgen rays. Hemoptysis was never produced, and forty patients treated by this method showed marked improvement both locally and in the general condition. Several of those who

took part in the discussion criticised the method, but Leyden spoke of it as being a welcome addition to the various other plans in use.

The physicians of Berlin are much interested in the monument to be erected in memory of Virchow. The commission has given the first prize to the design of the sculptor Klimsch, which portrays a man fighting against a fabulous monster, while Virchow's portrait appears only in a medallion on the base. The medical societies have protested against this selection, and would prefer a monument showing a full-length figure of the great pathologist. The commission has resolved to reopen the question, but no decisive action has yet been taken.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

RETURN OF CHOLERA—ORIGIN OF THE OUTBREAK—PECULIARITIES OF THE EPIDEMIC IN MANILA—GUARDING THE WATERSHED—PERSONAL NOTES.

MANILA, P. I., July 30, 1906.

A CHOLERA outbreak of considerable dimensions has occurred again in the city of Manila. For the week ending June 30 there have been sixty-three cases. The presence of the disease is undesirable at any time, but it is particularly unfortunate that it should make its appearance at this time of the year. The rainy season has just set in, and as the first two months of the same are usually characterized as the hot wet months, or, in other words, during July and August, cloudy skies, high humidity, temperature between 85° and 93° Fahrenheit are to be expected, it will be seen that the conditions are particularly favorable for the propagation of the cholera organism, as well as of flies, which are most likely to carry them about. The weather during these months corresponds closely to the conditions produced by the sirocco encountered in southern Europe, along the shores of the Mediterranean.

The disease had almost entirely disappeared from the Islands. Between May 22 and June 2 there was not a single case reported, either in the city or in the provinces. On this latter date, however, a case made its appearance in Pasig. From June 2 to 9 no further cases were reported. Upon this latter date, however, Pasig again showed three cases; June 12, four cases; June 14, five cases, and upon the 18th seven cases were reported. The importance of the presence of the disease at Pasig will be appreciated when it is understood that it is the center through which a large part of the traffic into and out of the provinces of Laguna and Rizal passes. It has a railroad line, river steamers, and wagon roads which lead in various directions. It has numerous market places and is a distributing center. On account of the foregoing, the appearance of the disease at Pasig is of considerably more importance than at many of the other provincial towns.

About June 18 the disease appeared more or less simultaneously in the towns of San Felipe Neri, Pandacan, and Cainta, in the province of Rizal; Siniloan, Pila, and Bay, in the province of Laguna; Malolos in Bulacan, and Angeles in Pampanga. The advocates of the theory that the disease is propagated by some fermentation or other mysterious process which goes on in the soil immediately came forward and pointed out that this was a full justification of their claims, but at best this explanation could not be regarded as satisfactory. It is thought more likely that the appearance of the disease at so many widely separated towns must be due to some more readily explainable cause.

A thorough inspection was made of the town of Pasig, and several days ago it was shown on fairly reliable testimony that a truck garden kept by a Chinaman had been fertilized with liquid human excreta. The annual religious pilgrimage, which took place this year during the month of May, to worship at the shrine of the Virgin of Antipolo, which is only a few miles from Pasig, lasts usually for thirty days, during which period it is estimated that upon some days as many as forty to fifty thousand persons are present. Investigation shows that in almost every instance the first persons who contracted the disease in the towns mentioned above were returning from Antipolo through Pasig, and had probably eaten some of the vegetables which were obtained in Pasig, and which were probably fertilized with some excrement which contained material from a cholera stool. A subsequent investigation has been made of this matter, and while it is difficult at all times to obtain thoroughly reliable information, still the evidence so far shows that in most of the towns in which the disease made its appearance, the first cases occurred among persons who had just arrived from Pasig. The secondary cases must have no doubt been due to contact.

In the town of Tanay, in the province of Rizal, there have already occurred 112 cases with 56 deaths. From Pasig the disease spread down the Pasig river toward Manila. The suburbs and outlying towns of Guadalupe, Pandacan, and San Felipe Neri soon became infected, and from these the infection spread to the city of Manila. During the week ending June 30 there were 63 cases, beginning with 2 on June 24 and ending with 23 on the last day of that week.

So far, the infection in Manila appears to be of a most virulent character. Practically all cases are found dead, the significance of which is that there are probably a large number of cases of cholera existing in Manila of which the health authorities know nothing, and in consequence the premises remain undisinfected, and each one is liable to become a center of infection. Unless the local physicians report cases more promptly, the advisability of prosecuting them is being considered.

Another noteworthy feature about the outbreak is the fact that the cases have occurred almost entirely among the poorer classes—none of the natives of the higher social scale, nor any Spaniards, Europeans, or Americans are so far known to have contracted the disease. This would indicate that the infection must be in the foodstuffs which are peculiar to the poor, but no particular food fits this description, unless it be the shellfish which they are in the habit of gathering near the mouths of the city sewers, some of the latter being probably infected. So far the cases have occurred in widely separated sections of the city. No two cases have occurred in any one house, nor in adjoining houses.

In view of the proximity of the disease to the Manila watershed, it was thought advisable to have the same guarded by the military. Accordingly the Governor-General requested Major-General Wood to detail a sufficient number of troops for this purpose. The troops proceeded to Mariquina the morning of June 28. In order that they may be vested with full authority, the Commission has passed a special act, which gives officers of the United States Army the authority of peace officers, and the power to make arrests of persons who violate the health regulations.

The municipal board of the city of Manila, in a special session held to-day, passed an emergency ordinance with a view to protecting the water supplies. It provides that the offenders may be brought to Manila and tried before the city courts.

Surgeon-General Rixey, U. S. Navy, arrived in Manila June 26, for the purpose of making a thorough inspection of the naval medical service in the Philippines. He has already inspected the new hospital which was recently completed at Cañacao, Cavite.

Dr. W. Ramsey Smith, head of the Health Department of South Australia, spent several days in Manila, during the week, in looking over the medical work being carried on here.

A WORD ABOUT RASHID, THE LEPER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Under the heading "Senseless Cowardice" you comment in your last issue on the alleged ill-treatment to which this leper has been and still is subjected. I am not in a position to offer any correction to that part of your comment which relates to the treatment which this man has received in other States, for the only source of information I have on this is the sensational daily press. But I am in a position to state that as far as this concerns the "wilds of West Virginia" you are in error. I inclose a copy of the *West Virginia Medical Journal*, the official organ of the West Virginia State Medical Association, and a copy of a local paper, both of which contain articles on this subject by reliable eyewitnesses. From these articles you will see that the "educated medical men" did do their duty and did "quiet the unreasoning fears of the public," with the result that both before the leper left this State and after his return to it he was treated with all the consideration due a fellow man. It is true that he has been isolated, but every needed comfort was furnished him in the tent with which he has been provided, and a more permanent shelter for him is now in the process of erection. At the expense of the county in which he is now located a regular physician residing in the immediate vicinity is looking after his health. So far as this State is concerned, the newspaper reports can hardly be characterized as exaggerations; they are falsehoods. WILLIAM W. GOLDEN, M.D.

ELKINS, W. VA., Aug. 20, 1906.

The Uses of Etiquette.—Medical etiquette, instead of being kept up, as people so often imagine, in the interests of the doctors, is maintained in the interests of the public. It is they, not the doctors, who would suffer most were it done away with.—*The Spectator.*

Progress of Medical Science.

Boston Medical and Surgical Journal, August 16, 1906.

The Serum Treatment of Exophthalmic Goiter.—G. A. Waterman refers to the various theories as to the cause of this condition and records his experience in the use of serum derived from blood drawn from the jugular vein of the goat two weeks or more after the removal of the thyroid, the serum being used subcutaneously. Of the five cases reported, two were considered as cured, two improved, and one unimproved. He thinks that in the serum treatment we have an agent which influences the disease favorably, and may, with further modification, prove to be of more uniform value. It may be along this line or by the use of the cytotoxic serum, that we shall be able to find a specific means of relieving the distressing symptoms of a most troublesome disease.

New York Medical Journal, August 11, 1906.

Puerperal Fever Treated by Uterovaginal Drainage.—A. Ernest Gallant says that the excellent results obtained by the use of his bivalve cervical drain in cases of early miscarriage, sterility, and dysmenorrhea due to obstruction (see MEDICAL RECORD, November 22, 1902, page 836) seemed to warrant the enlarging of this drain and its adaptation to the cervical canal of the uterus recently emptied during the latter months of gestation. This keeps the internal os well open and does not plug up with blood and serum. The diameter is large enough for the introduction of a catheter through which to introduce irrigating fluids without removing the drain. The bivalve drain not only affords easy exit for the lochia, but acts as a foreign body and excites uterine contractions and promotes involution. During the puerperium the woman should not be allowed to lie upon the back, but always upon the side or abdomen. A few cases are related, illustrating how the drain works when in practical use.

Gleanings Concerning Menstruation.—James Oliver in 1887 endeavored to show that the menstrual discharge in the human female was not a concomitant of a more or less extensive shedding of the uterine mucosa, and clinically it was difficult to believe that it essentially was an outpouring of blood from vessels whose integrity had been destroyed by a gross process of disintegration. Speaking generally the uterus behaves like a glandular structure, and it is to this behavior more especially that he draws attention. He recapitulates Heape's description of the changes observed by him in the case of the *Semnopithecus;* he speaks of four menstrual periods which are subdivided into eight stages. In speaking of the stage of formation of the menstrual clot Heape says: "The full extent of the act of denudation is reached, the severe action disclosed being almost worthy of the term devastating. All over the body and fundus of the uterus the superficial portion, about one-third of the mucosa, including uterine and glandular epithelium, stroma and blood-vessels, is cast away, leaving behind a ragged wreck of tissue, torn glands, ruptured vessels, jagged edges of stroma, and masses of blood corpuscles, which, it would seem hardly possible, could be satisfactorily healed without the aid of surgical treatment." It is evident that our knowledge of the mechanism and utility of the menstrual function, and of the structures which participate directly in the production of the menstrual discharge itself, is still very meager. Regarding the evolution of menstruation we know absolutely nothing.

The Importance of Abdominal Examination Before Insurance.—Samuel P. Gerhard believes that the examination of the abdomen is woefully neglected by most medical examiners for insurance, and he relates a case to show the importance of greater care in the examination of applicants, and the great annoyance that could be averted if examiners were more thorough.

The Function of the Testicle.—Hubert Richardson says that the changes produced by castration are confined principally to the genitalia and breasts, the bones, the skin and appendages, the muscles, the glands and internal organs, the larynx, the skull, the brain, and the mentality, differing according to the age at which the operation is performed, and with the sex. After considering the effects of castration upon the various tissues and organs of the body he closes his article by calling attention to the serious constitutional effects which follow castration in the young; and as, according to the last United States census, one in every three hundred and twenty of the population is either insane, criminal, or a pauper, the impracticability of the scheme of compulsory emasculation of criminals, feeble minded, idiots, insane, epileptics, etc., is self-evident. In any case resecting the vasa, leaving the testicle intact, is the maximum operation which should be permitted.

Journal of the American Medical Association, August 18, 1906.

Tumor of the Carotid Gland.—W. W. Keen and J. Funke report a case of the rather rare tumor of the carotid gland, an inconstant organ located between the forks of the common carotid artery. Up to date twenty-seven such cases have been reported as operated on and two have been found at postmortems, making twenty-nine in all. The authors think from the increased number of cases observed of late years, however, that such growths are not quite so infrequent as has been supposed. It is the deformity it causes and the occasional rapid growth of the tumor in its later stages that call for surgery, but on account of the involvement of the vessels and of the vagus in the tumor, and the consequent dangers of the operation, Keen advises against meddling with it except in cases of very rapid growth and threatening malignancy. Abstracts of the cases reported in the literature are given, and the diagnosis, symptoms, embryology, histology, etc., are discussed at length. A better knowledge of the normal gland would facilitate the study of these growths, but the lack of this has led to considerable confusion in their classification. Funke suggests that in view of all the facts they may be called endotheliomata.

Infection in Acute Lymphatic Leukemia.—P. Marvel reports a case, calling attention particularly to the following features: 1. A pain in the leg of unknown cause, which was the first disturbance of the previously existing good health. 2. A slowly progressing anemia, coincident with menorrhagia. 3. An acute attack of tonsillitis followed by enlargement of the lymphatic glands of the face, neck, axilla, and groin with the thyroids, liver, and spleen. 4. The absence of pathogenic change in the blood cells at the beginning of the tonsillitis attack and its appearance some time within the following twelve days, as evidenced by the second examination that was permitted. The diagnosis was supported by the following clinical symptoms: Rapidly progressing anemia, conspicuous predominance of lymphocytes, general debility, pathogenic change in the lymphatic glands, enlargement of spleen, liver, and thyroids, early appearance of petechiæ, ecchymotic or purpuric areas, hemorrhagic dyscrasia, gastrointestinal irritation, and, associated with the latter part of the illness, profuse sweating. The clinical evidences pointing to infection in this case are, he says, strikingly similar to those recognized in scurvy, sepsis, and other accepted bacterial diseases. He thinks, therefore, that the streptococci or the streptococcic toxins of the tonsillitis had much to do with the pathogenic change of the lymphatics and blood tissues and incidentally with the serious metabolic disturbance, functional failure, and death which followed.

Gastric Hyperacidity and Gastric Symptoms.—J. D. Steele, with a view to confirming Stockton's theory that the symptoms credited to gastric hyperacidity are due mainly to a hyperesthesia of the gastric mucosa, and to ascertain what other factor might also be effective, has studied thirty cases under his observation. In about one-half of his cases the cause of the irritation and pain lay in the existence of decided gastric motor insufficiency or of hypersecretion. In fourteen, however, no cause could be demonstrated for the hyperesthesia, but in nearly all of these the gastric symptoms were directly connected with overfatigue or worry, or were a part of a general nervous irritability. All the patients were benefited and ultimately cured by treatment directed to the nervous condition. This, with the fact that the symptoms do not appear to depend necessarily on the amount of acidity and may be absent when it exists to a very high degree, seems to indicate that in these cases it was the local manifestation of a general state of nervous irritability. This was the view taken by Kaufmann, Stockton, and Musser, each of whom have reported similar cases. The practical bearings of this on the treatment are obvious, as that for the neurosis must differ from that of cases due to ulcer, retention, or hypersecretion. Steele finds a liberal mixed diet nonirritating to the sensitive mucosa, and the use of nerve sedatives, together with agents to relieve acidity, most useful. His experience also agrees with that of Musser as to the value of nux vomica, in doses slowly ascending to the physiologic limit, in the treatment of these cases.

Antitetanic Serum.—H. J. Scherck reports the results of the use of antitetanic serum for Fourth of July injuries in that city. A few days before the Fourth a large amount of the serum was obtained, put up in packages of 10 c.c. with everything complete and thoroughly sterilized, and kept in an icebox at a suitable temperature. Beginning about the 4th and extending to about the 7th of the month, 170 cases were treated in the city dispensaries. They included almost every possible Fourth of July injury, but not a single case of tetanus developed; repeating in this the experience of the previous two years in which the serum was employed. In 1903, before the use of the serum, 56 cases were treated, with 16 deaths from tetanus. In 1904-5 37 and 84 cases respectively, with no deaths, and in the present year 170 cases, as stated. To test the efficacy of the serum four guinea-pigs were inoculated with the minimum lethal dose of tetanus toxin. Two of these were treated with the minimum protective dose for their weight, and a third with four times this amount. The fourth pig received no protective injection, and showed tetanic symptoms in 16 hours after the inoculation, and died eight hours later. None of the others showed any symptoms whatever of tetanus. In the dispensary patients treated, in a few cases, there was a slight rise of temperature on the day following the injection, but no other symptoms were produced. In a few cases the injection was made in from two to four days after injury, and still proved prophylactic.

The Lancet, August 4, 1906.

Blood Pressure and Pigmentation in Addison's Disease.—A. Rendle Short records a case of Addison's disease, on which many observations were made on the blood pressure, and he summarizes as follows: (1) The symptoms of Addison's disease are due to vasomotor paralysis. This is due to absence of adrenalin, the normal excitant of the sympathetic nerve endings, from the blood. (2) The pigmentation is due to vascular relaxation of the skin, causing exaggerated functional activity of the pigment cells. (3) The most promising line of treatment, on theoretical grounds, is the administration of vasoconstrictors of prolonged action, and digitalin has given good results in one case.

Caterpillar Rash.—John C. Thresh says that every few years some entomologist suffers from an urticarial rash, due to handling caterpillars or their cocoons. Because children collect caterpillars in order to see the transformation into a butterfly, he claims that unless a note of warning is sounded cases of caterpillar rash will become more frequent.

On Some of the Pseudo-Parasites of Cancer.—Albert S. Grünbaum roughly classifies the pseudo-parasites as resulting from (1) cell degeneration; (2) cell inclusion or either leucocytes or other cells; (3) cell derivatives, *e. g.* the spermatid vesicle; and (4) non-specific organisms. He claims that a proper classification is often difficult, and may frequently afford ground for differences of opinion. Illustrations accompany the article.

A Case of Acute Rheumatism; Hyperpyrexia; Recovery.—E. Bertram Smith reports such a case occurring in a man, aged 54 years. On the eighth day his temperature by mouth was 107.2° and his pulse 128. An ice pack was used and just before applying it the temperature rose to 109.3° in the rectum. After three-quarters of an hour in the pack the temperature dropped to 107° and the ice was discontinued. Only two cases could he find recorded in the British literature of recovery after so high a temperature had been reached in rheumatic hyperpyrexia, and in both of these cold baths had been employed.

British Medical Journal, August 4, 1906.

Landry's Paralysis.—Eric Macnamara and Julius Bernstein give the full details of such a case which, from a clinical standpoint, is a typical one. The motor symptoms were those of a gradually ascending flaccid palsy, and these amounted to so high a level that on the eleventh day of the illness ocular movements were impaired. Thereafter the symptoms gradually retrograded. Throughout there were no sensory symptoms nor any incontinence of feces or urine, and eventually recovery was complete. Several microorganisms have been noted by various observers as occurring in the tissues of these patients, and they conclude that an organism resembling a tetracoccus isolated from a similar case post mortem was existing in an active condition in the blood and cerebrospinal fluid of a patient with Landry's paralysis, from which he recovered. And though the evidence is insufficient to definitely point to it as the causal agent, in the light of bacteriological findings in other acute infections the association is suggested. Further, it helps to confirm Buzzard's post-mortem findings in a similar case.

Notes on a Case of Fissura Abdominalis.—Howard Stevenson reports such a case occurring in a seven to eight months premature female child. Two hours after birth a large mass of bowel lay exposed outside the abdomen without peritoneal or other covering. This mass consisted of large and small intestines, with a patent Meckel's diverticulum. Operation was performed when the child was two and a half hours old. The fissure was between one and two inches long; this was enlarged and the intestines replaced. The abdominal wall was sutured, the umbilical cord being fixed in the upper angle of the wound. The child died on the eighth day.

Ascaris Lumbricoides as a Cause of Appendicitis.—Aldo Castellani reports the post-mortem findings in such a case, and shows a photograph of the appendix containing a worm. The worm was firmly inserted into the appendix, and could not be pulled out, although much force was applied. The post-mortem findings clearly prove that ascarides under certain circumstances may be the cause of appendicitis.

Gumma of the Brain.—F. H. Jacob reports the case of a man, aged 50, who was seen to be apparently unconscious. There was incontinence of feces and urine and the right arm was completely paralyzed. There was a marked drop of the right angle of the mouth, and paresis with rigidity of the right leg. Both knee jerks were active. On the penis was a large papilloma thought to be syphilitic. Under the use of the iodides and mercury he improved greatly, possessing perfect movements of the face, arm, and leg, but with some weakness of the right arm.

Münchener medizinische Wochenschrift, July 31, 1906.

Regarding Proteolytic Ferment Action of the Leucocytes.—Muller and Jochmann stated in a former communication on this subject that the blood from a case of myelogenous leukemia would promptly digest Loeffler's serum at 50° C., but not at the temperature of the body. They attributed this to the fact that the ferment action was only rendered possible by the rapid death of the myelocytes owing to the high temperature, and that it was inhibited at ordinary temperatures by certain elements in the blood. It was claimed by Stern that perhaps the plasma contained inhibitory elements which lost their activity at the temperature noted. The present paper by Muller and Jochmann deals with the answer to this claim of Stern's, and as the result of their present series of experiments they conclude that the leucocytes of the normal human blood as well as those from leukemia, fresh pus, and bone marrow, are deprived of their digestive powers by the addition of blood plasma or serum at a temperature of 50-55° C., although at this temperature they still develop a well-marked ferment action even when diluted with physiological salt solution. This shows, according to the writers, that Stern's contention is unfounded.

An Improved Method of Displaying the Spirocheta in Smears.—Hoffmann and Halle call attention to the fact that in making thin smears when looking for this organism, cells and nuclei are apt to be destroyed and the detritus thus obscures the field under observation. A method is desirable by which the search may be prosecuted even in thicker layers of the material to be examined. That proposed by the authors is as follows: Into a flat glass dish of about 5 cm. diameter there are placed 5 c.c. of a 1 per cent. osmic acid solution and 10 drops of acetic acid added. This is placed in a Petrie dish in order to avoid the irritating vapors from the osmic acid. Carefully cleaned cover glasses are then exposed to the acid for 2 minutes, and while they are still moist, the material for examination is passed over the surface with a single sweep. Then the cover glass is immediately returned to the dish for another minute or two. The fixed specimens are then dried if necessary, but preferably without heat, and placed in a dilute solution of potassium permanganate for a minute, after which they are washed in water and dried with filter paper. The staining with eosin is completed after the manner advocated by Giemsa. It is claimed that the spirochetes in these preparations may be readily distinguished and the cells and tissue bits in the field are intact and so do not obscure the picture.

A Case of Bacteriemia without Symptoms.—Künzel reports a case in which the symptoms during life afforded no clue whatever to the true condition present, which on autopsy was determined from the examination to have been sepsis. The organs were practically

negative and presented nothing which should have brought about a fatal issue, but a chance examination of the blood showed an abundance of streptococci. Microscopical preparations of the tissues confirmed these findings. Although these streptococci were universally distributed throughout the body, the patient had had no rise of temperature, nor were there any other symptoms present which would warrant the suspicion of such a severe septicemia. It would seem wise, therefore, to institute a bacteriological examination in every case where the pathological examination failed to disclose the cause of death.

Deutsche medizinische Wochenschrift, August 2, 1906.

Chorea Gravidarum.—Martin, from his many opportunities to observe this condition, is convinced that in the majority of mild as well as severe cases the pregnancy need not be interrupted, but that medical treatment is almost always successful. In only three cases has he found it necessary to produce abortion, but as soon as this was done recovery always resulted after a longer or shorter period. In two cases he also had an opportunity of treating chorea in the same patient in several successive pregnancies, a rather unusual occurrence. In one of these cases there was no history of any previous organic disturbance or infectious disease; in the other the chorea followed an attack of articular rheumatism. In a discussion of the treatment of these cases, Martin states that the induction of abortion should only be considered as a last resort, and then only in patients where there is present a severe endocarditis, meningitis, or similar complication. The result is often fatal, and this is not usually due to the chorea itself, but to apparent liability to puerperal infection which these patients present, although this has been lessened since the introduction of bougies or tents for the purpose has been abandoned and anterior colpohysterotomy substituted. As regards medicinal treatment, he has had good results following the administration of the bromides (bromide of soda and ammonium aa 2,0; bromide of magnesium, 4,0) together with careful attention to nursing and feeding.

Streptococcus Mucosus as a Cause of Otitis Media.—Wittmaack, in endeavoring to clear up certain points in the bacteriology of middle ear disease, made use of the procedure advocated by Schottmuller, by which it is possible to separate well-marked varieties of streptococci growing on agar and blood culture media. As the result of this method the following varieties may be distinguished: *Streptococcus erysipelatos, viridis* and *mucosus.* Careful studies made in 55 cases seem to show that in addition to the other varieties of streptococci, the *Streptococcus mucosus* apparently plays an important rôle in the production of an acute otitis media, and that this variety is, moreover, the most virulent when tested by injection into mice. If the disease was due to the mucosus, its course was usually protracted (four to five weeks), and if due to the diplococcus, it was much milder and apt to last only about two weeks. The former variety of infection seems also more apt to be complicated by mastoiditis.

Changes in Virulence in Pathogenic Organisms.—Loeffler discusses the liability of all organisms, whether plant or animal, to be influenced by external factors, among which food and temperature are the most important. This applies particularly to the lower orders of plants, including the bacteria, so that it becomes possible by artificial means to reduce or increase the virulence of these organisms to an extent without limitation. This acknowledged change in the pathogenic character of bacteria led Loeffler to experiment with the organism of foot-and-mouth disease, which is very virulent in cattle, but less so in sheep and swine. He endeavored to make this organism more virulent for the less susceptible animal and then to observe whether such cultures would lose in virulence by the process when injected into cattle. If this fact could be proved, then the modified organism might be used for prophylactic vaccination in cattle exposed to the disease. He was able by successive inoculations of the cattle lymph in young pigs to produce a lymph which, although very virulent for the latter, produced little reaction when injected into cattle and provided a degree of immunity against the disease which lasted several months. The method seems harmless and suitable for practical purposes. It will be further developed by the author.

French and Italian Journals.

Use of Hot Solution of Soda in the Disinfection of Floors.—Giuseppe Pecori calls our attention to the lack of efficiency of the solutions of corrosive sublimate in ordinary use for disinfection of walls and floors. He finds comparatively useless many disinfectants ordinarily used. In order to obtain a disinfectant that would be efficient for the disinfection of hospital floors, as well as the rooms used in infectious cases, the author has made experiments as to the value of solutions of soda used hot for the destruction of the tubercle bacillus and other common germs. He finds that solutions of soda of 2 per cent. used hot and kept in contact with the bacteria for from five to ten minutes are not to be relied upon to destroy the bacilli, but that if solutions of 5 and 10 per cent. be used hot and applied for five or ten minutes they are efficacious and destroy all the bacilli. He believes that such solutions have a very real value in the disinfection of walls and floors, and that at the same time they are not at all injurious even to cement floors. Another advantage is that the solutions are exceedingly cheap. The commercial soda that is an oxyhydrate and contains 70-72 per cent. of sodium hydrate is the one that should be used.—*Gazetta Medica di Roma,* May 15, 1906.

Contribution to the Surgery of the Gall Bladder and Cystic Duct.—Mario Segre has been impressed by the changes in the gall-bladder walls that are found in cases of malignant disease of the gall-bladder on the post-mortem table. He has made experiments on rabbits by producing complete or partial stenosis of the gall ducts to find out what changes were produced in the walls of the gall-bladder and cystic ducts. He finds that the epithelium of the gall-bladder is first affected; later the muscular fibers undergo degeneration; finally all layers are transformed into connective tissue. In cases of incomplete stenosis the muscle of the gall-bladder undergoes hypertrophy and there is an attempt to push the obstructing calculus away. When atresia is complete this process does not take place. In the incomplete cases there is danger of an ascending infection of the ducts, owing to the biliary stasis which exists. In incomplete atresia there is a favorable condition set up for the formation of calculi. In complete obstruction there seems to be no use in conservative treatment of the gall-bladder, since it soon becomes degenerated. The author advocates cholecystectomy, since the patient readily adapts himself to the absence of the organ.—*La Riforma Medica,* June 2, 1906.

Acute Poisoning with Quinine in Infants.—Osvalde Federici draws our attention to the comparative frequency with which acute poisoning by quinine takes place in infants. He had the care of a patient of sixteen months of age, who secured a bottle of quinine confections in his mother's absence, and swallowed between twenty and twenty-five of them, estimated at about 4.5 grains. Within two hours and a half the child had died of acute poisoning, with nervous symptoms predominating over the gastric ones. There was vomiting and congestion of the stomach and intestine, with post-mortem ulcerations found in the stomach, but the predominating symptoms were those of collapse and convulsions, followed by coma, in which the child died. At the autopsy no other changes were found in the internal organs than those already mentioned. The author concludes from his observations that acute quinine poisoning in infants and in animals produces no marked lesions of the digestive organs. The form in which the drug is administered makes a difference in the degree of poisoning, a soluble salt acting quicker and more powerfully. There is great difference of opinion as to the poisonous dose in infants, and there is need of further accurate study in this direction.—*Rivista di Clinica Pediatrica,* May, 1906.

Relations of the Menstrual Function and Mental Diseases.—Aleardo Salerni says that in normal women there are always nervous symptoms accompanying the coming of the menstrual period. In those affected with mental troubles there is almost always irregularity of menstruation, amenorrhea, or menorrhagia. In many mental states there is a distinct exacerbation of the disease at the time of menstruation, but there are no special typical symptoms at that time, simply an increase of the ordinary symptoms of the disease. The author believes that there is no causal relation between these menstrual irregularities and the mental diseases. There are always other etiological factors present. At the same time, the occurrence of menstruation has a marked effect on the course of the disease. In the periodic forms of mental disease this relation is marked, and such diseases often first appear at the menstrual period. The chronic mental diseases are rarely accompanied by menstrual irregularities. The toxoinfective forms are most affected by menstrual irregularities. In arrest of development regularity of menstruation is in direct relation with the physical development of the subject. Cases of periodic mental disease and arrest of development are always observed to undergo an attack of agitation at the arrival of the menstrual period, which continues as long as the flow lasts, and increases to a climax, to decrease toward the end of the flow.—*Il Policlinico,* May, 1906.

Book Reviews.

Consumption. Its Relation to Man and His Civilization. Its Prevention and Cure. By John Bessner Huber, A.M., M.D., Fellow of the New York Academy of Medicine; Member of the National Association for the Study and Prevention of Tuberculosis, etc. Philadelphia and London: J. B. Lippincott Company, 1906.

It is no easy task to write a book on a medical subject that, while fully within the grasp of lay comprehension, shall also be of value to the physician; yet Dr. Huber has attempted this, and has succeeded admirably. While there are already several excellent works on tuberculosis intended for the instruction of nonmedical readers, the present volume is probably the only book of this class likely to be directly useful to physicians also. The author has planned his work on the broad, generous lines of German scientific writing, but has, in addition to this thoroughness, managed to inject into it a more distinctly literary quality than is usually met with in the medical books of to-day. The text is divided into fifteen parts, devoted respectively to general considerations, the etiology of the disease, predispositions to tuberculosis, sociological factors, factors relating to the home, prevention, the cure, and the means to this end, American and European sanatoria, the sanatorium and its adjuncts, administrative measures, nongovernmental activities, and a scientific résumé. In a series of appendices, the matter of disinfection, plans for the erection of tents and shacks, data relative to the cost and construction of sanatoria, etc., are given, as well as very useful lists of American societies and committees for the prevention of tuberculosis, and of sanatoria. Much information in regard to the tuberculosis situation that is essential to the physician, but has not yet found its way into the ordinary text-books, is given, and the discussions of the climatic and fresh air treatment contain many hints likely to be of the greatest assistance in managing individual patients. The sociological aspects of tuberculosis also are treated most interestingly, and the reforming of the conditions under which the poor in great cities are compelled to live is given extensive consideration. Interesting illustrations are scattered through the volume, and we warmly commend it to the physician, both for his own perusal and for use among his patients.

Outlines of Applied Anatomy, with Special Reference to Surface Landmarks. By Richard J. A. Berry, M.D., F.R.C.S.E., F.R.S.E., Professor of Anatomy in the University of Melbourne, formerly Lecturer on Anatomy in the School of Medicine of the Royal Colleges, Edinburgh; and Examiner in Anatomy to the University of St. Andrews, to the University of Aberdeen, and to the Royal College of Surgeons, Edinburgh. With forty-six illustrations. Edinburgh: William Green & Sons; Philadelphia: J. B. Lippincott Company, 1906.

This work is a concise presentation of the subject of applied anatomy brought down almost to the form of a compendium. As stated in the preface, the author has endeavored to bridge over the gap between anatomy as studied in the dissecting room and its practical application in hospital wards. It consists in a systematized series of brief anatomical descriptions, with especial reference to surface landmarks clinically applicable. The diagrams and illustrations, while in many instances not original, are helpful. The book is well adapted for hasty reference, but is not exhaustive and is not pleasantly readable, as is the case with some other recent works on applied anatomy. Its chief recommendation lies in the conciseness of the author's treatment of the subject.

Reference Handbook of the Diseases of Children. For Students and Practitioners. By Prof. Ferdinand Fruhwald of Vienna. Edited, with additions, by Thompson S. Wescott, M.D., Associate Professor of Diseases of Children in the University of Pennsylvania. With 176 illustrations. Philadelphia and London: W. B. Saunders Company, 1906.

It is always a good plan to read the preface of a work; sometimes it conveys more information than the title page, and often it may be the means of preventing disappointment. In the present instance we learn from the preface that this compendium is not designed to take the place of a text-book, but that it is intended to prepare and stimulate the student for the study of text books and to serve as a convenient clinical guide. We further learn that, as far as treatment is concerned, this work is simply an epitome of the pediatric therapeutics at present in vogue in Vienna. If these two facts are remembered, the book will cause no disappointment. The subjects are arranged alphabetically, beginning with abscess and ending with zona. There are numerous cross references, some of which appear unnecessary; for example, the average medical student is hardly likely to look for agrypnia when he wants insomnia, or for arthrogryphosis in place of tetany. On the other hand, even a student might possibly be tempted to look for articles on empyema, or tonsillitis, or dysentery, or foreign bodies in the nose; if so, disappointment is in store for him. In the discussion of the various topics, symptoms and treatment receive ample attention, while pathology and diagnosis are practically ignored. The treatment is at times decidedly heroic, and has to be modified by the American editor; the editorial pen might well have been drawn through several preparations unknown in this country, as well as through the half-page of names of European baths, etc., suggested as being beneficial in scrofulosis. We do not think the present work is especially suitable for the American medical student; and whatever may be its reputation in Germany, it is not likely to attain a high rank here.

Materia Medica and Therapeutics. An Introduction to the Rational Treatment of Disease. By J. Mitchell Bruce, A.M., LL.D. (Hon.) Aber., M.D. (Lond.), Fellow of the Royal College of Physicians of London; Consulting Physician to Charing Cross Hospital and to the Hospital for Consumptives, Brompton; formerly Examiner in Medicine in the University of Cambridge and Examiner in Materia Medica in the University of London and in the Victoria University. New and Enlarged Edition, Revised Throughout, and containing the Indian and Colonial Addendum to the British Pharmacopœia. Forty-ninth thousand. First American Edition, with the Formulæ Adapted to the United States Pharmacopœia, by Oscar Oldberg, Ph.D., Dean and Professor of Pharmacy in North Western School of Pharmacy. Chicago: W. T. Keener & Co., 1906.

As we have so recently reviewed Bruce's Materia Medica and Therapeutics (see Medical Record, February 10, 1906), there is no need of a lengthy notice on the present occasion. For a long time this book has been most favorably known in England and Canada as one of the very best text-books on the subject; and it has been a matter of surprise to us that there has been no revision of it to conform to the requirements of practitioners using the United States Pharmacopœia. And now, in this first American edition, it is to be regretted that the editor did not thoroughly adapt it to the U. S. P. by introducing the numerous preparations of our Pharmacopœia which are not found in the B. P. Possibly, when another edition is called for, we may have this masterly and popular work made suitable to our needs and requirements.

Neurotic Disorders of Childhood. Including a Study of Auto- and Intestinal Intoxications, Chronic Anemia, Fever, Eclampsia, Epilepsy, Migraine, Chorea, Hysteria, Asthma, etc. By B. K. Rachford, M.D., Professor of Diseases of Children, Medical College of Ohio, University of Cincinnati; Pediatrist to the Cincinnati Good Samaritan and Jewish Hospitals; Member of the American Pediatric Society, of the Association of American Physicians, etc. New York: E. B. Treat & Co., 1905.

This excellent and most readable book is a development of a series of articles published originally in the *Archives of Pediatrics* some ten or twelve years ago. These articles were entitled "Some Physiological Factors of the Neuroses of Childhood," and as revised they constitute the main portion of Part I in this book. Three other chapters have been added on Gastrointestinal Toxemia, Autointoxication, and Chronic Systemic Bacterial Toxemias. This part is in the nature of an introduction dealing in general terms with the undeveloped and irritable nervous system of the child, and its reaction in the different pathological conditions of anemia, toxemia, autointoxication, etc., in response to reflex initiations, and in states of excessive nerve activity. The second part deals practically with the various neuroses, their causation, symptoms, and treatment. The book will be of service to the pediatrist as well as to the neurologist; indeed, it is written rather from the viewpoint of the former. It treats chiefly of the homely but practical questions of the cure of the neuroses of childhood, and concerns itself less with speculations regarding the pathology and morbid anatomy of these diseases. It is an eminently practical book and one that will often be of great assistance to the general family practitioner.

Das Wesen der Psychose auf Grundlage Moderner Naturwissenschaftlicher Anschauung. Von Dr. Heinrich Stadelmann. Heft V: Die Paranoia; Heft VI: Die Epilepsie. Munich: Otto Gmelin, 1905.

This is an analytical study of the Psychoses or as the author has it "The Psychosis," implying a common substratum for Hysteria, Epilepsy, Paranoia, etc. Stadelmann dissects the psychological, physiological, chemical and physical phases of the psychoses and reviews critically the various opinions held as to these factors. To him psychological dissociation in a chemicophysical phenomenon of polarity. In the present section he deals with epilepsy and with paranoia.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-fourth Annual Meeting, Held at Toronto, August 21, 22, 23, 24, and 25, 1906.

GENERAL SESSION.

(Special Report to the MEDICAL RECORD.)

First Day—Tuesday, August 21, 1906.

THE meeting was called to order at 2 P. M. in the Convocation Hall and prayer was offered by the Rev. Dr. McLaren.

Valedictory Address from the Retiring President.—Mr. GEORGE COOPER FRANKLIN, F.R.C.S., of Leicester, said it was his privilege as *laudator temporis acti* to refer to the past year's work, and he spoke of the admirable and most excellent work of the British Medical Association, the time and devotion given by the gentlemen who managed to be members of the Council, of the Committees, of the Representatives, etc.

Induction of the New President, Richard Andrews Reeve, B.A., M.D., LL.D., Dean of the Faculty of Medicine, University of Toronto. In his induction a badge was given him, a locket inside of which was a protograph of his own child, the Convocation Hall. The badge of office was presented by Dr. F. N. G. Starr.

Reception of Delegates from Colonial Branches and Distinguished Visitors.—This reception of delegates, distinguished visitors, members of various American medical societies, was marked by much applause.

Recommendations of Council.—It was moved, seconded and carried most enthusiastically that Mr. George Cooper Franklin, F. R. C. S., and Sir Victor Horseley, F. R. C. S., F. R. S., be and are hereby elected Vice-Presidents of the British Medical Association for life, in accordance with By-Law 38, for their distinguished services to the Association.

Addresses of Welcome.—Address of welcome to Toronto was made by His Worship the Mayor; in behalf of the local reception committee by Mr. Irving H. Cameron, M. B., F. R. C. S., LL. D.; of the Canadian Medical Association by the President, Dr. Alexander McPhedran; and of the Ontario Medical Association, by the President, Dr. George A. Bingham.

Presidential Address.—RICHARD ANDREWS REEVE, B. A., M. D., LL. D., reviewed in lengthy detail the advances made in medicine and surgery, especially during the past decade, and ended his address by stating that the members of the British Medical Association had come to this country at a critical period in their history, at a time in the making of a nation; that the profession in Canada had not exceeded in loyalty the standards based on the traditions of the profession. He referred to the bill in the House of Commons, introduced by Dr. Roddicks, a bill standing for an idea and an ideal, "Dominion registration and reciprocal action on the part of Great Britain and the daughter, Canada."

Dr. HENRY BARNES, LL. D., of Carlisle, offered a resolution, which was seconded by Dr. T. G. Roddick, LL. D., F.R.C.S., of Montreal, that the best thanks of the Association be given to Dr. Richard Andrew Reeve for the scholarly and interesting Presidential address on the occasion of the seventy-fourth annual meeting.

Address on Obstetrics.—Dr. W. S. A. GRIFFITH of London delivered this address at the evening session. He referred in the introduction to former orations on obstetrics delivered at meetings of the British Medical Association, of which there had been only a few. The first, in 1863, was by Dr. J. G. Swayne of the British Medical School, and it was interesting to note that of the many subjects discussed in this address, the obstetric use of chloroform, version in cases of obstructed labor, the treatment of placenta prævia, cesarean section, blood-letting and chloroform in puerperal convulsions, the nature of thrombosis and of phlegmasia dolens, and the operation of ovariotomy, almost all were still matters under discussion. The second address, in 1884, was given by Dr. G. H. Kidd of Dublin, who took as his subject Puerperal Fever, which he handled chiefly from the clinical point of view. The next address was delivered by Dr. Cullingworth at Newcastle, in 1893. The subject was Pelvic Peritonitis in the Female, and the Pathological Importance of the Fallopian Tubes in Connection Therewith. The address remained as a landmark in our knowledge of the pathology of salpingitis; it led to the general appreciation by British gynecologists of the true pathology of perimetritis, as well as to advances in abdominal surgery in the treatment of these cases. In 1900 an address was delivered at the meeting of the Association at Ipswich by Dr. W. J. Smyly of Dublin, the subject being Maternal Mortality in Childbed. Its chief importance as a landmark was in its indication of the simplification of antiseptic measures for the protection of parturient women, as, for instance, the abolition of the douche as a routine practice, and in its insistence on the substitution as far as possible of external or abdominal for internal or vaginal examinations during labor. Finally, at the meeting at Manchester in 1902, Sir William Japp Sinclair discussed Carcinoma in Women, chiefly in its clinical aspects. In this address he expressed his firm conviction that the secret of cancer would be discovered (if ever) by the study of cancer of the uterus. Dr. Griffith then entered upon a discussion of the subject of his address, which was "The Teaching of Obstetrics." He reviewed the practice which obtained in this respect in London, and offered suggestions for the improvement of the methods now in vogue. The author closed with a eulogy of the late Dr. Matthews Duncan, who went to London to fill the vacant post of obstetric physician at St. Bartholomew's Hospital in 1877.

SECTION ON SURGERY.

First Day—Tuesday, August 21.

THE PRESIDENT, SIR HECTOR CLARE CAMERON, M.D., OF GLASGOW, IN THE CHAIR.

Posture as an Aid in Surgery.—Dr. MURRAY MCLAREN of St. John, N. B., read this paper. He said the objects of posture were variable, and the desired results were obtained in many ways and through different channels, mechanical, anatomical and physiological factors to be considered. A natural and restful position of the patient was to be desired, with an avoidance of pressure upon certain areas of the body. Posture was of importance in the relief of pain, vomiting, dyspnea, in drainage, hemorrhage, in the prevention of the entrance of fluids into the air passages, and also in the avoidance of pulmonary complications. He considered the Simm's, the geniopectoral, Pryor's, Trendelenburg's, Rose's, Fowler's and other positions. Posture should be particularly considered in the administration of anesthetics, in the prevention of syncope, in the prevention of the inhalation of saliva, and the prevention of aspiration pneumonia. Posture was considered also in the post-operative treatment and in the relaxation of muscles following fractures.

Dr. IRVING H. CAMERON of Toronto believed that the dorsal decubitus was man's prerogative of rest, and should not be slighted. The only other animal that ever rested on its back was the dog, and this position of rest was given us for a purpose that should not be ignored.

Dr. CARMALT of New Haven, Conn., spoke of the reversed Trendelenburg position in the treatment of septic peritonitis with free pus in the abdominal cavity, and called attention to the report of Fowler's thirteen cases, in which the head

of the bed was raised fourteen inches. The upper part of the abdominal cavity was where pus was the more easily absorbed, and, by raising the head of the bed, quicker and more perfect absorption was favored.

Dr. Liston H. Montgomery of Chicago discussed the paper.

Fracture-Dislocation of the Spine.—Dr. A. Beverley Welford of Woodstock read this paper, and considered as involved only that part of the spine extending from the base of the skull to the lower border of the first lumbar vertebra, with its accompanying complete motor and sensory paralysis and absence of important reflexes from compression or laceration, or both, of the cord substance. After such an injury the question arose, what should be the proper course to pursue? An attempt should be made at reduction by extension and counter-extension, and evidence of its successful performance might be given by hearing the peculiar click, and by noting that the spinous processes were in normal line. One might be successful in replacing the dislocated parts, but there still might not be relief of the compression upon the cord; in fact more injury might be done than good by lacerating or compressing the cord. The question again arose, how long to wait for symptoms to show that improvement had taken place ? If symptoms showed no relief in from two to eight weeks, he said they had a right to assume that, although pressure had been relieved, the cord had been so much damaged as to be incapable of functionating. In case of uncertainty, he asked, why not do a laminectomy at once? He advocated earlier operation, and related two interesting cases that he had operated upon.

Enlargement of the Prostate and Its Treatment.—Mr. Lynn Thomas, C. B., of Cardiff opened the discussion of this subject, and said that during the past five or six years there had been quite a revival of interest in this subject, and some of the most remarkable successes had attended work on the enlarged prostate, especially in the aged. He had tried to formulate certain rules for his guidance in attacking the variable pathological conditions of enlarged prostate. Persons the victims of prostatism should not be submitted to enucleation if there was contraction of the orifice of the urethra, or if there was a fibrous prostate. He believed the middle lobe was more commonly the seat of pathological changes than any other. He also quoted from authorities to show that the capsule was intimately connected with the stroma and also the outer surface of the fascial sheath of the prostate. He asked, under what circumstances should the prostate be enucleated? When the catheter life became established patients preferred operation. He considered the operation to be safer than the continued use of the catheter. The vast majority of patients who use catheters two or three times a day sooner or later become septically infected. He had done 29 suprapubic and 2 perineal operations. He had looked up the statistics, only those in which ultimate results were given, in Europe and in America, and he found as follows: The total number of perineal prostatectomies was 677; of suprapubic prostatectomies, 583. The total recoveries from the perineal operation showed 89.58 per cent.; in the suprapubic, 88.9 per cent. The deaths directly due to the operation by the perineal route amounted to 6.8 per cent.; the suprapubic route, 7.7 per cent. The remote causes of death in both operations was exactly the same, 3.54 per cent. The recoveries from the operation, showing complete cures was 81.4 per cent. for the perineal, and 95.6 per cent. for the suprapubic operation. So far as the death rate was concerned, the statistics showed an advantage of 1 per cent. in favor of the perineal route. So far as complete cures were concerned, 14 per cent. was in favor of the suprapubic route. The perineal route was the more favorable for drainage from the bed of the cavity left after prostatectomy; if the suprapubic route was chosen it might be well to institute additional drainage by a perineal incision. In septic cases the operation had better be done in two stages. Here followed a description of his technique. In his conclusions he stated that there was no choice between the suprapubic and perineal operations so far as accidents or mortality were concerned. In both operations, there sometimes followed strictures of the urethra, fistulæ, etc. The suprapubic route should not be undertaken by surgeons with short fingers. It was not possible to remove the prostate in one mass without removing the whole of the prostatic urethra.

Dr. Robert F. Weir of New York said the two important points to be decided upon at the present time were first, in prostatic difficulties when was the best time to attack that organ; secondly, what was the better route for attack? The earlier attempts were made on those patients when there was nothing else to be done and when this was the only operation to perform; and then the kidneys and bladder were involved and the mortality was made high. Even to-day the statistics show that the mortality was heavy, ranging between 9, 12 and even 14 per cent.

Dr. G. A. Bingham of Toronto gave a description of the microscopical structure of the prostate, which showed a lack of true capsule, the definite lobes being absent. Embryologically, the prostate was shown to be purely sexual in origin. The pathological changes in hypertrophy were taken up to show the relationship of the newly formed tissue to the remainder of the gland. It was contended that in the modern operation of prostatectomy enucleation was performed through the outer part of the gland, and that a portion of the prostate was always left behind. He then considered the question of a "middle lobe." Three classes of cases were discussed under treatment: (1) The early cases, where the only symptom was obstruction; here enucleation was advised, with catheter life as the alternative. (2) The very late cases, in which was advised permanent drainage of Bottini's operation. (3) The intermediate cases when enucleation was the best treatment. He held that neither perineal nor suprapublic prostatectomy met all indications. He closed his remarks with statistics, which favored the perineal route of approach.

Dr. Arthur T. Cabot of Boston said he only did the suprapubic operation in those few cases of old men with feeble organs, where it was necessary to make a short operation, or where the patient had a third lobe which had to be removed by short anesthesia. He believed the perineal operation to be the one of choice. The functional results following the perineal operation were so much better than those following the suprapubic, or the partial, or the Bottini operation that he now adopted it as the method of choice. The preparation of patients for operation was an important thing. For instance, cases that were profoundly uremic when first seen were those that gave high mortalities if operated upon at once. Most of them could be placed in good shape for operation by adopting catheter drainage through the urethra until the tongue cleared up, the appetite returned, and the patient recovered his strength; operation then could be done with safety. Such drainage had an extraordinary effect upon the kidneys; the urine became remarkably increased and there was an improved elimination in the amount of urea. After operation good results followed from simply good drainage and an occasional irrigation, keeping the bladder clear of clots. He now removed the perineal drainage earlier than formerly.

Dr. Teskey of Toronto favored the perineal approach, believing the operation to be the more easily performed and the drainage more effectual and less time taken in its performance. He could find no argument favoring the suprapubic operation. Statistics were wanting regarding the sexual function after operation.

Sir Hector Clare Cameron of Glasgow reported an interesting case upon whom he operated sixteen years ago. At that time there were no surgical writings on this subject. When he saw the patient, a man 46 years of age, he had been using the catheter for years and he suffered

much pain. He had absolute retention and the only urine passed was by catheter. It was an extraordinary fact that he had been sounded for stones, but none found. He had been suffering from severe attacks of hemorrhage and the bladder had become much distended with blood which had putrefied; this was accompanied by an enormous distension of the bladder, due not to blood and urine alone, but from gaseous putrefaction. He believed that few realized the enormous distension of the bladder which often took place. When the knife was used stinking gas came from the bladder and thirteen stones (five of large size) were removed. Having removed these stones and putrid clots a large drain was introduced, the wound stitched and a wait of six weeks was made, when a second operation was performed. Then the pathologist reported an adenomyomata of the prostate. Sixteen years after the operation the patient remained in perfect health, except, following such enormous distension of the bladder, there was still no power left to empty it completely.

Dr. E. E. King of Toronto believed the suprapubic route the better, as the operation could be carried out in his experience more quickly and more thoroughly. He used two large drainage tubes; one he removed at the end of thirty-six hours, the other at the end of seventy-two. The irrigation was continued every eight hours, but not with a pressure over eighteen inches in height. As a rule too much pressure was used. He was particularly interested in Sir Cameron's case, in which the patient was almost moribund. He firmly believed that in years to come the suprapubic operation will be the one of choice.

Sir William Hingston of Montreal believed that, all things considered, the suprapubic operation was the better one, but that both operations were followed too frequently. The operator himself should decide what operation to do.

Dr. Francis J. Shepherd of Montreal related the history of a case operated on by him in 1892, the patient being 50 years old. To-day he was perfectly well. He preferred the suprapubic operation.

Dr. W. Alexander of Liverpool had had over 200 old men under his care for years, and yet he scarcely ever found occasion to operate for prostatic enlargement. The operation was performed too often. He preferred the suprapubic route.

Dr. D. J. Williams of Llanelly, Wales, preferred the suprapubic approach.

Dr. H. A. Bruce of Toronto believed the more rational method of approach was the suprapubic. Many cases of prostatic enlargement should not be operated upon at all; cases should, in his opinion, be more carefully selected.

Dr. William J. Mayo of Rochester, Minn., President of the American Medical Association, said that in the work done at Rochester the perineal operation was more often performed, they doing three or four perineal operations to one suprapubic. The perineal operation, when gotten at from the urethral side, gave a shorter convalescence. There was no particular difference in the mortality rate. But, when the perineal operation was done, the patients were in bed one week or less, and left the hospital within three weeks; whereas, in the suprapubic operation, there was a tendency to develop fistula, and they remained in the hospital one month or more. There was about ten days saving of time, but there was the same mortality. In some cases the suprapubic operation was to be preferred; for instance, when there was a tendency for the tumor to rise in the bladder. Most of the cases had to be cystoscoped and the tumor examined to see which method was the one of choice. But whichever way the tumor presented was the easiest way to remove it. He called attention to the high percentage of malignancies, not less than 15 per cent. of enlarged prostates showing malignancy at some point and in the tumor itself. This he believed to be an important fact, and well worth remembering. This was particularly important, as it might enable them to eliminate a certain percentage of the cases of malignancy previous to operation. Again, this fact called for a comparatively earlier operation.

Dr. Ochsner of Chicago chose more often the perineal route. He believed in first thoroughly exposing the prostate by a horseshoe incision. He called attention to the similarity in removing a prostate and the vaginal removal of the uterus. The operation was much facilitated by placing in sharp retractors and drawing the gland downward, so that the field of operation was entirely under control. One should keep in mind the venous plexus about the prostatic urethra. In those cases where enucleation was very difficult Ferguson's forceps were of great aid.

SECTION ON MEDICINE.

First Day—Tuesday, August 21.

Sir Thomas Barlow, M.D., President of the Section, in the Chair.

President's Address.—Sir Thomas Barlow said that with a program so full as that of this section and with so much interesting material, it seemed idle to take up time with an address on the "Aims and Scope of Medicine" or some like conventional topic, as was so often done. After a single word of cordial appreciation for the honor of being selected to preside over the section he preferred simply to announce the excellent papers that were to be read and allow the section to proceed with its work. He could not refrain, however, from complimenting his Canadian brethren on the modesty with which they had kept themselves in the background and placed the names of visiting members and guests of the Association prominently on the program. The papers for this first morning on "Blood Pressure in Its Relation to Medicine" were an excellent example of the thoroughgoing work of the committee and doubtless would be epochal in their statement of the most recent advance in diagnosis.

Physiology of Blood Pressure.—Dr. Percy M. Dawson of Baltimore, Md., opened the symposium on Blood Pressure on Relation to Disease with a paper on the physiological aspect of the question. He said that much confusion had arisen from the fact that the word blood pressure had been used without specifying just what form of blood pressure was intended by the term. Personally, he had never used the term without putting an adjective before it. Systolic blood pressure was that which depends upon the force of the heart. Diastolic blood pressure was that which resulted from the various tendencies to bring blood back into the heart. The pulse blood pressure is really the systolic blood pressure minus the diastolic blood pressure. Whenever the term is to be used, then, Dr. Dawson preferred to use the plural—blood pressures. Dr. Dawson said that the problem of blood pressure might very well be illustrated by means of a curve or figure in which the various forms of blood pressure were represented by abscissas and ordinates. For each case these had to be calculated if the exact idea of what was intended by the real blood pressure was to be worked out. In all cases the question of the resistance offered to the initial energy of the heart must also be considered, and this added to the complexity of the problem. In a word, the study of blood pressures was by no means simple, and would require careful investigation before physiological knowledge could be applied for therapeutic purposes.

Clinical Investigation of Blood Pressure.—Dr. G. A. Gibson of Edinburgh discussed the various modes of investigating blood pressure for clinical purposes. The work of the heart, he said by way of introduction, was modified by many extrinsic factors. Blood pressure owed not a little to the peripheral resistance. This was very changeable. The abdominal vessels ruled by the splanchnic nerves also modified general

blood pressure. The elasticity of the arteries transformed potential into kinetic energy, and this must be taken into account. Viscosity was also a factor, though its importance was not well understood. There was a layer of blood constantly in contact with the vessel walls, and as this was quite immobile friction was generated and resistance to flow occurred. Dr. Gibson did not agree with those who consider that the educated touch, *tactus eruditus,* was quite sufficient to enable the physician to recognize the quality of blood pressure. To insist on this was to put oneself in the position of those who would say that temperature might be judged by means of the finger also. The position was antedeluvian, or at least antiquated. Much help could be derived from the use of blood-pressure instruments in pneumonia; the change of blood pressure represented the point of danger. A drop below the ratio that went with the pulse rate was the herald of death. In typhoid fever, the increase of blood pressure indicated by the instrument was the signal often of an outbreak of nervous symptoms. It was easy to realize even from these examples how important the use of instruments for the estimation of blood pressure might be. The speaker said that the best principle of measuring blood pressure was that employed originally by Riva-Rocci. This consisted of a band around a member. It was important, of course, that this band should be broad enough, otherwise the result obtained was too high. The sphygmomanometer invented by Erlanger gave both the diastolic and systolic blood pressure in graphic tracings, and was undoubtedly the best instrument. Other instruments were useful, but contained dubious elements and liability of error. Another method employed was that of noting the tint of the skin for blood-pressure purposes. While this had certain elements of truth, it was not as useful, in Dr. Gibson's opinion, as the method of direct measurement of pressure. He considered that it was extremely important to take certain precautions with regard to the measurement of blood pressure. The posture of the patient was extremely significant. The patient must be in a horizontal position. Excitement made a very great difference in the matter of blood pressure. This might occur even in the doing of things with which the patient was very familiar. Dr. Gibson found that his own blood pressure, which was normally about 150 during the course of a lecture, rose to 190, or even higher. It was easy to understand, therefore, that patients who came for the first time to a strange physician might very well suffer from so much excitement that the blood-pressure tracings obtained from them would have very little real significance. A number of observations ought to be made, and blood pressure should be kept on charts just as the temperature is. In a word, the instrumental methods of measuring blood pressure promised to give a new and very helpful set of facts for diagnostic purposes.

Pathology of Blood Pressure.—Sir William Broadbent, M.D., of London said that the question of the *tactus eruditus,* the trained finger, appealed to him very much, and though he might seem antediluvian, he still had to express the opinion that with the finger one could recognize very well all the variations of blood pressure for which special indications could be found in therapeutics. It would be amusing to consider blood pressure instruments in country practice. Exact instruments were only of use to educate the touch. Blood pressure depended to a great extent on the resistance in the capillaries. The viscosity of the blood depended not entirely on the stickiness of the blood particles by which they cohered to one another, but also on the tendency of the blood to stick to the walls of the blood-vessel. This adhesion, indeed, was the main cause of the delay of the blood in the capillaries. Many unexpected factors influenced blood pressure. Cold and heat, for instance, and excitement, were extremely important. The persistent small pulse of hysteria every physician knew. The vascular atony of neurasthenia was also well recognized. In the speaker's opinion the best criterion of normal blood pressure was the radial artery. If this could be emptied readily by the pressure of the finger, then there was no serious change in blood pressure. It was with regard to this that the education of the touch was most important. In fat people there was often a small pulse and artery. In thin people the artery was often large and round, yet the question of emptying by pressure could be used on both classes of patients and some definite ideas as to the comparative blood pressures could be obtained. He said that the heart might readily be interfered with by pressure upon it from the diaphragm. The right ventricle was especially likely to be affected. It rested upon the slope of the diaphragm. When this muscle was stretched, as because of the presence of gas in the abdomen, or because of a distended stomach, then there was a reduction in the general blood pressure because there was not blood enough passed on by the right ventricle to the lungs, and thus to the left ventricle, to keep up the blood pressure. When the pulse is too rapid, enough blood did not get in and out of the heart to keep up the general circulation, and the conesquence was a drop in blood pressure. This factor was sometimes neglected. When the heart was weak, then stimulants must be used. If there was resistance in the capillaries, then this must be reduced. For the purpose nitroglycerin, tetranitrin, and the nitrites were the most important drugs. Sir William Broadbent considered that to decrease the action of the heart was nearly always a mistake. Increase of heart action was always compensatory. This might become dangerous, but only too often a willing heart was disturbed by depressant drugs in its faithful overwork. The conditions of the blood must be modified so as to decrease viscosity. This could be done by withdrawing the calcium salts, as well as the ordinary salts, from the body. Alkaline waters acted not so much directly as by eliminating poisons that were in the system. Mercury was, however, the most important drug for this purpose in his experience. Mercurial aperients accomplished more than any other single set of drugs.

Blood Pressure and Arterial Sclerosis.—Dr. T. Clifford Allbutt of Cambridge, England, discussed the relationship of blood pressure to degeneration of the arteries. Increase of blood pressure, he considered, was due to something inside the circulation or something outside the circulation, or to the normal decay of the arteries. The factors within the circulation were toxins. These were usually due to infections, though they might be the results of the introduction of such substances as lead or alcohol into the system. Outside the circulation were certain organic changes, as for instance granular kidney, which made the work of the heart harder and somehow led to degeneration of arteries. With regard to overeating as a cause of increase of blood pressure, it was to be borne in mind that this was very individual. Some persons could eat large quantities and suffered not at all. Others ate relatively small quantities, yet showed distinct signs of disturbance. Usually it was considered that increase of blood pressure led to arterial sclerosis. Dr. Allbutt had seen blood pressure rise without producing arterial sclerosis. He had seen arterial sclerosis without rise of blood pressure. At times arterial sclerosis advanced so far as to defeat the heart without material rise of blood pressure. He had seen a preliminary thickening of the arteries in the early stage of arterial sclerosis apparently which had been due to rise of blood pressure, but which disappeared, showing that the thickening was only a compensatory action on the part of

the muscular coat. Dr. Allbutt considered that arterial tension was a bad term for pressure in a living tube. The term arterial sclerosis itself was not a clinical, nor even a single pathological entity, but rather represented a series of changes due to a number of different causes and conditions.

Forms of Arrhythmia.—Dr. J. MacKenzie of London, England, discussed the elements that went to make up the heart's contribution to blood pressure. They have been catalogued as Gaskill's functions under these names: tonicity, excitability, rhythmicity, contractility, and conductivity. Keeping these in mind, Dr. MacKenzie said that every form of arrhythmia could be traced to a definite cause. He said that the sphygmograph had been derided by many, but that was because they expected to obtain results from it for which it was never intended. A man might complain that a hand saw did not shave well, but that did not condemn the saw as useless. The sphygmograph was not meant to study blood pressure, but the character of the pulse. Dr. MacKenzie had often seen exhaustion of the heart occur without dilatation, and even rupture of the heart might occur as the result of overwork in these conditions. The therapeutic lesson was not to stimulate the heart, but to lessen resistance.

The Trained Finger.—Dr. Lindsay Stevens of Glasgow said that the trained finger was better in estimating blood pressure than any instrument. Many factors militated against the accuracy of instruments. Dr. Stevens had never seen high tension cause arterial sclerosis. He considered that high tension might be an effect but not a cause of arterial sclerosis. Both were due to poisons in the blood. Syphilis and lead had been mentioned, but every infectious disease produced a poison that increased blood pressure and also caused some degeneration of arteries.

Instruments Absolutely Necessary.—Dr. Alexander McPhedran of Toronto said that all forms of instruments for measuring blood pressure were on exhibition in the exposition. Any one who had used an instrument for measuring blood pressure realized how impossible was any proper judgment of difficult cases by means of the finger. If any one still believed in the *tactus eruditus*, disillusion came at once after even a little experience with an instrument. Dr. McPhedran cited many cases and showed that the instrument also helped in the decision as to whether a particular line of treatment should be followed. When the nitrites produced no fall in blood pressure, then this could be determined by the instrument and the uselessness of further nitrite giving realized.

Spasm in Blood Pressure.—Dr. McCaskey of Fort Wayne, Ind., said that the most important feature of blood pressure was the peripheral resistance, and this was often due to spasm of the arterioles. This could be overcome by drugs, showing that there had been no arterial change. The prognosis of such cases was better than had been anticipated. Organic degeneration of arteries was not preceded by high arterial tension, but this was an effect of the arterial sclerosis.

Arterial Sclerosis and Pain Symptoms.—Dr. Alfred Stengel of Philadelphia said that in certain cases arterial sclerosis was accompanied by fever and chills without any other cause, and abdominal pains also occurred as a consequence of arterial degeneration. Where fever and chills had been observed, careful search had been made for gall stones, pus in the kidney, inflammation of the gall bladder, cystitis, and for any lesion of the prostate. Even autopsies had been made without finding anything. The abdominal pains were quite marked and had been observed by many excellent physicians. Ortner in Vienna had described a case with cramplike pain. Osler had seen a similar case. In Dr. Stengel's experience a patient had repeated attacks, and it was seriously considered that an exploratory incision should be made in order to determine whether the appendix was affected or not. Finally, a very severe attack occurred and suppression of urine and uremia followed, with fatal termination. At the autopsy no appendicitis was found and no other inflammatory condition to account for the pain. There was a high-grade arterial sclerosis of the abdominal vessels. Altogether, twenty-five cases of abdominal pains associated with arteriosclerosis have been analyzed. Some of them were found to be angina pectoris, giving its symptoms in the abdominal region. Most of them, however, showed a high-grade arterial sclerosis of the intraabdominal vessels, but no other lesion to account for the pains. Thrombosis was not necessarily present, though this frequently terminated the scene. There was a suggestion in these cases of the intermittent claudication which occurred in the legs occasionally in association with arterial sclerosis. When there is an aneurysm of the abdominal aorta, then there was always sure to be pain and tenderness. The tenderness is more marked than the pain, however, and the characteristic attacks such as were described in ordinary arterial sclerosis did not occur.

Muscular Hypertrophy.—Dr. Ewart of London said that all persons engaged in active occupations had a certain development of the muscular coat of their arteries that made their arteries palpable. He had noticed this in examining cases in his wards when he found that seamstresses and others who did no manual labor did not have palpable arteries even at an advanced age very often, though the young women who did hard manual labor had quite palpable arteries even at twenty or under. Hence the importance of recognizing the influence of the occupation. Rest was the most important thing to keep off the change which led to the aging of the arteries. Sleep with its definite tendency to lessen blood pressure was the best possible preventive of precocious senility. Next to this rest in a horizontal position was the most important. All the factors had to be taken into account, or the relation of cause and effect in blood pressure and arterial sclerosis could not be properly understood.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

Second Annual Meeting, Held at Washington, May 17 and 18, 1906.

(*Continued from page* 196.)

(Special Report to the Medical Record.)

SURGICAL SECTION.

Thursday, May 17.

Dr. W. W. Keen of Philadelphia in the Chair.

Tuberculous Peritonitis.—Dr. Richard Douglas of Nashville read this paper. He said that 16 per cent. probably represented the frequency with which tuberculous peritonitis occurred in tuberculous subjects. In the 5,687 intraperitoneal operations in St. Mary's Hospital, Rochester, Minn., 3 per cent. were for some variety of tuberculosis, and out of 883 collected autopsies upon tuberculous children Biedert had found peritoneal involvement in 18.3 per cent. Tuberculous peritonitis was but one of the local manifestations due to the action of the tubercle bacillus. The statement that it was always secondary was practically unchallenged, yet in view of the conclusive proof furnished by Walsham, he felt that evidence would soon be forthcoming that the peritoneum, like many other structures in the body, might be the primary site of the lodgment of the bacillus. He classified the channels of infection as (1) hereditary transmission; (2) lymphatic vessels; (3) blood-vessels; (4) epithelial channels; (5) inoculation into the skin and other tissues. In speaking of prognosis Dr. Douglas said the effects of operative treatment had been to teach us that tuberculosis was often present without producing special symptoms and with a natural tendency to recover. Peritoneal tuberculosis appearing as a part of general miliary tuberculosis offered little hope of even temporary arrest. The subacute and

chronic ascitic forms were most amenable to operative treatment. In only exceptional instances should operation be undertaken in the fibrous form. All forms except the peracute were at least temporarily benefited. He considered that in general miliary tuberculosis medicinal and hygienic measures only should be employed; in dry fibrous peritonitis surgical measures should not be resorted to except to meet complications, as intestinal obstruction; in peracute cases, those of violent onset resembling appendicitis, the expectant treatment should be preferred. In the ascitic form he thought the simple incision not sufficient; the exudate should be completely removed, but efforts should not be made to detach adherent viscera further than to free encapsulated fluid. He thought the general conclusion justified that tuberculous peritonitis can be cured by laparotomy. The unsuccessful cases were those that had advanced disease in other organs. Operative results, he said, give a recovery rate of from 25 to 30 per cent. The prognosis after treatment by both medical and surgical methods had been carefully studied by Shattuck; out of the ninety-eight cases treated, the end results were known in fifty-seven cases; twenty-five of these were treated medically; the ultimate mortality, reaching to a period of eleven years, was 68 per cent.; thirty-two cases surgically treated, mortality 37.5 per cent. From these figures it was learned that cases of tuberculous peritonitis might recover under simple medical treatment, and evidence was not wanting to show that an anatomical restoration might be obtained.

Dr. Wm. Litterer of Nashville, Tenn., in the discussion of this paper, said that for the past year he had been conducting experiments upon animals (dogs, guinea pigs, cats, etc.) with the view of ascertaining whether it was possible to produce tuberculous peritonitis from the alimentary tract without involvement to the wall of the gut, or of the mesenteric or retroperitoneal glands. He said the open question as to whether we could have a primary infection of the peritoneum was answered in the negative by such men as Veit, Nothnagel, Vierodt, and a number of recent writers. The results of his experiments had been only partially successful in so far as demonstrating a primary peritonitis was concerned, but in the course of the investigations he had been able to demonstrate the passage of the tubercle bacillus through the normal intact mucous membrane without showing any evidence of lesion at the point of entrance This was the opinion of Walsham, Harbitz, Theobald Smith, Ravenel, and many others. Baumgarten's views, he said, ran counter to this, for he insisted that the bacilli always produce some lesion at the point of entry. He gave a résumé of the experimental work he had done, and said the investigations would be published in detail subsequently.

Dr. Alexander Ferguson of Chicago said that tuberculous peritonitis ran a course of more or less destruction uninfluenced by any known drug or combination of drugs that had been administered for its relief; like many other diseases within the abdominal cavity, it entered the realm of surgery just when the patient was sliding into eternity. When laboratory workers should have discovered a cure, probably a serum, capable of cutting short its progress, or obtaining results superior to operative procedures, then the surgeon would rejoice in reassigning the disease to the physician. The abdomen should be opened below the umbilicus in acute or subacute cases as soon as the diagnosis was made, or to make a diagnosis; the hand to be passed in to feel every structure within the peritoneal cavity in search for a primary focus, and having found it, it should be removed, whether it be the Fallopian tubes, uterus, ovaries, appendix, gall-bladder, or section of bowel. He said a turbid, or milklike fluid should not be washed out because the phagocytes in it were the principal curative agents provided by nature, but clear ascitic fluid should be washed out, as it had no curative power. Then the cavity was to be filled with physiological salt solution with iodoform emulsion (10 per cent. in glycerin) applied to the diseased parts. The speaker cited two cases to illustrate that early surgical interference was not contraindicated in acute tuberculous peritonitis. In chronic tuberculous peritonitis he often opened the abdomen over the most prominent part, explored with the hand, broke down cheesy material, liberated encysted fluid, flushed away tuberculous débris with saline solution, mopped dry, and smeared with iodoform emulsion. Intraabdominal tuberculous abscess was treated by evacuation, insertion of iodoform emulsion, and drainage.

The Treatment of Tuberculosis of the Bones and Joints.—Dr. Joel E. Goldthwaite, Boston, read this paper. He held that if the patient was otherwise in good health there was no reason why the area of disease should at once be excised. If to save life it was necessary to sacrifice a part, it should by all means be done; but he thought we should be very sure first that such radical measures were required, a part lacking much of its function being better than the best artificial contrivances. He thought the general treatment should not be overshadowed by surgical measures; that every hygienic measure should be used just as in tuberculosis of the lungs; life absolutely in the open air, in tents or shacks, or specially ventilated rooms, plenty of sunlight, and good feeding. This, of course, was also the best preventive measure. Local treatment, he said, should consist in the preservation of function of the part without increasing irritation at the site of the disease. Just as it was important to exercise the lungs in pulmonary tuberculosis, so he thought it was necessary when the disease attacked the bones and joints and function should be allowed up to the limit of toleration. In this way, he said, healing took place much more rapidly than when limitation of function made all the parts sluggish. He believed that conservative measures should be given a thorough trial until other lines of treatment became advisable. The operation to be performed in a given case, of course, depended upon the part affected; amputation or the entire removal of the affected part might in some cases be demanded, but at least a short period of conservative treatment under favorable conditions should first be urged. The presence of an abscess, he said, was generally first made known by interference with the function of a part, and the mere presence of an abscess, so long as it did not interfere with function, was of little importance while it remained closed. He thought if the abscess and the primary focus could be removed at the same time it would be desirable to do so; but it had to be borne in mind that a free opening was not desirable, as it offered a fresh port of entrance to infection. He thought many deaths were due to systemic infection in this way and not to the local tuberculosis. He advocated aspiration in such cases rather than free drainage. He believed that if the treatment of tuberculosis of the bones and joints were carried out along these lines the results would be better.

Dr. Wisner R. Townsend of New York said that, owing to the great advances that had been made of late years in the knowledge of the etiology and pathology of the diseases affecting the bones and joints, the question of diagnosis was deserving of special consideration at the present time. Until recently, he said, all chronic affections of the bones and joints occurring in childhood were considered to be due to tuberculosis. Arthritis caused by infection from pneumococci, streptococci, staphylococci, gonococci, colon and typhoid bacilli, and other pathogenic microorganisms were classed as tuberculous. The arthropathies occurring in nervous diseases were often erroneously included with the above, and the same was true of lesions of scurvy and the infectious processes occurring in measles and scarlet fever. Rheumatism and tuberculosis had been the two diseases supposed to cause most of the diseases of the bones and joints. Even coxa vara and fracture of the neck of the femur in children had been classed as hip disease. To-day, the speaker said, these conditions could be easily and positively made out, and the profession was keenly alive to the necessity for greater proficiency in diagnosis. The addition of the *x*-ray as an aid to such diagno-

sis had already proven of great value, and its use should be encouraged. He thought that too much attention should not be paid to the presence or absence of tuberculosis in the family history, but that the tuberculin and other tests should be thoroughly tried in surgical tuberculosis in order to ascertain their real value as aids to diagnosis. He considered tuberculosis of the bones and joints a most serious condition, and one that needed the greatest care in treatment, both constitutional and local. Outdoor life, supplemented by surgical and orthopedic treatment, was justly meeting with great favor. He thought there was no reason why mild cases of tuberculosis of the bones and joints should not entirely recover. Most operations were performed when sepsis was already a serious factor, and this should be guarded against. Mechanical treatment should be employed, he thought, from the beginning, but not continued blindly after sepsis had occurred. Apparatus of varying types should be used to preserve and restore function when possible.

Dr. A. T. Cabot of Boston said that surgical tuberculosis was, in the vast majority of cases, a process secondary to some deeper infection, the primary focus being usually in the lymphatic system, connected either with the respiratory or digestive organs. The treatment should be general and local, hygienic and operative. He thought it was the physician's first duty to put the patient in surroundings of air and sun such as had abundantly proved their efficiency in the cure of all forms of tuberculosis; secondly, he should provide in every possible way for the fullest nutrition; thirdly, he should give the diseased parts rest by apparatus which interfered as little as possible with the motion and exercise of the unaffected parts of the body; fourthly, after these fundamental needs had been provided for he should proceed by operative measures to remove or alleviate local conditions; fifthly, it was his duty to protect the community from contagion, and to this end he should teach his patients to destroy all discharges from tuberculous processes; sixthly, he should impress his recovered patients with the importance of so arranging their business or occupations that they might be able to pass a large part of their time in the open air, and so guard against a recurrence of the disease.

Dr. B. E. McKenzie of Toronto was pleased at the emphasis laid upon the matter of diagnosis by Dr. Townsend, but he had come to look upon it as a rather certain factor now, and would not be inclined to attach as much doubt to it to-day as Dr. Townsend had. There were three elements of particular importance to be considered, viz., heredity, lowered vitality, and infection. As to the rest as an element in the treatment he thought a good deal depended upon how the rest was secured. He thought that much of the orthopedic apparatus used in hip disease and disease of the spine was antiquated and out of date; he did not believe the apparatus could keep the spine even fairly well at rest. He advocated the use of the Bradford frame, and said that with it a great advantage was that the child could be kept out of doors. As to amputation he thought that when there was but one lesion, as in one limb, amputation might sometimes be an important conservative measure. As to abscesses, they might be left alone very largely. As to the position of the leg, he thought there should be flexion of from 5 to 15 degrees.

Dr. Joseph Bloodgood of Baltimore said the paramount object of treatment was the cure of the disease with complete function of the joint, the latter being the most difficult to obtain. The three factors in treatment were local rest of the diseased part, surgical intervention in selected cases, and the general hygienic treatment of the patient. To accomplish a cure with restoration of joint function depended more upon early recognition of the disease than any other factor. The public, therefore, had to be educated to the early symptoms suggesting lesion of the bone or joint, and it was necessary that the general practitioner should be keen in his differential diagnosis. He believed that in all forms of surgical tuberculosis the open-air or hygienic treatment was usually incomplete. He impressed the fact that treatment locally and generally should be continued months, and perhaps years, after symptoms had disappeared. The indications for surgical intervention were manifold and varied with the age, duration of the disease, and extent of the lesion. He thought that the employment of Bier's method had not been given proper consideration in this country. He was skeptical as to the value of injections of iodoform, etc. In children operation was contraindicated, as a rule, in all stages. In case of abscess better results were obtained by direct attack of the bone focus than by any treatment of the abscess itself.

Dr. W. S. Baer of Baltimore said he heartily agreed with those who thought that in the treatment of tuberculosis the less operative work that was done the better, particularly in cases of children, but there seemed to him to be a certain class of cases occurring after the age of fifteen in which it was possible to recognize a very early tuberculous focus in which the disease should be attacked radically. With the aid of the *x*-ray and tuberculin a pretty definite idea could be obtained of the condition. It seemed to him better to eradicate a small focus when possible than to risk a prolonged treatment. He agreed with Dr. Goldthwait in regard to allowing the joint motion within certain limits.

Dr. S. von Ruck of Asheville, N. C., desired to call attention to the use of laboratory products of the tubercle bacillus, and said that for the last two years he had been experimenting with various culture products in a series of 2,000 cases and had been convinced of the value of this method, used in conjunction with dietetic and hygienic treatment. He had had remarkably good results, he said, in the treatment of joint tuberculosis.

The Surgical Treatment of Tuberculous Glands of the Neck.—Dr. Charles H. Mayo of Rochester, Minn., presented this communication. He said the lymphatic system was increasingly appreciated for its protective and nutritive value as well as for its action in maintaining metabolism, but that until recently it had received scant attention from anatomists, and at present the great majority of the profession did not consider the glandular system except when gross evidence of disease was present. The defense function was important, and it was not unusual for the glands to sacrifice themselves in resisting invasion. He reviewed the anatomy of the lymphatic system and said that when a gland was found enlarged the first thoughts that would arise were: What is the infection? Where did it gain entrance? If a number of varied groups were diseased we had to ask what was the general or constitutional cause of the manifestation. In the cervical glands the most probable source of entrance would be the nose, throat, ear, scalp, or teeth. By far the most common source of infection apparently was the tonsil. The high percentage of tuberculosis found in the tonsil had been surprisingly instructive. The first node involved and palpable was usually the tonsillar gland, felt in the space behind the angle of the jaw. There were many lymph glands in the parotid structure, and when primarily involved by tuberculosis it usually meant that the infection had come from the middle ear. The postpharyngeal glands, when involved by tuberculosis, were likely to liquefy and open into the cellular space behind the pharynx, developing a postpharyngeal abscess. He believed that radical operations in very acute tuberculosis were questionable procedures. He classed treatment as non-operative and operative, the first including general hygiene, medicinal, *x*-ray, and congestive therapy. The prophylactic operative included the removal of the tonsils and adenoid tissue in the young. Direct surgical treatment he considered as palliative and radical. He believed that tuberculous glands were best treated by their removal, as the glands as such were destroyed by the disease, while the bacilli might be held for an indefinite period, ready to develop in case of a lowered state of vitality of

the patient. The radical operation should be a complete one for the removal of the group or groups involved. Muscles, as a rule, should be left uncut and the essential motor nerves intact.

Dr. Floyd W. McRae of Atlanta said the point made by the writer with reference to complete removal of primary foci was an important one, but it was a matter not easy of accomplishment. Tuberculosis within the substance of the parotid gland, he said, was very difficult of diagnosis; he had made the mistake of thinking it sarcoma, and had to change the diagnosis on opening into the structure. With reference to treating the open wound he had had no experience with the various iodine solutions, but had confined himself to carbolic acid, followed by alcohol and temporary drainage with silkworm gut, as first suggested by Ferguson of Chicago. These were left in twenty-four hours and drained out the excess serum.

Dr. John H. Gibbon of Philadelphia said that this form of tuberculosis was one which appealed to surgeons, because if there was one form of tuberculosis which the surgeon sees that may be considered as localized it was this one. He considered the question of diagnosis a most important one, and thought it was only in recent years that differentiation had been attempted. In the earlier stages of the disease it was desirable to try the alteratives, with hygienic and climatic treatment. He was especially convinced of this when one group of glands only was affected. With outdoor life, such alteratives as arsenic and iodides in some form, particularly hydriodic acid, improvement occurred. When the trouble was chronic and when suppuration had taken place removal of the glands was advisable.

Dr. A. H. Ferguson of Chicago said the first thing looking to a diagnosis was to inspect the nose, throat, and mouth carefully, and to have any abnormal condition there corrected. He deprecated the use of the *x*-ray, unless in connection with suitable change of climate. He did not think the kind of incision materially mattered. He deprecated the complete operation where there was a mixed infection. The only case he had lost was one in which he had operated, in spite of a mixed infection.

Dr. W. W. Keen of Philadelphia said he had never followed the practice of dividing the sternocleido muscle, as he had always found that by lifting it he had been able to get access to the glands with perfect ease. The principal glands to be removed were those in immediate contact with the jugular vein, and occasionally, though rarely, with the thoracic duct. Injury had occurred more frequently to the thoracic duct in the removal of sarcomatous glands because of the greater adhesions. He said he was a strong advocate, and had practised for years, the thorough extirpation of these glands. He removed every gland he could find, big or little, because he was sure the smaller ones would become enlarged, as they were probably already infected. He had found it often difficult to make the diagnosis between tuberculous glands and Hodgkin's disease, but he had found that in the tuberculous glands much more commonly there were chains of glands matted together which could be distinguished as individual glands in a mass, rather than the enlarged single glands met with in the earlier stages of Hodgkin's disease.

(*To be Continued.*)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 23, 1906

Dr. Floyd M. Crandall in the Chair.

Report of Cases Presenting Mild Constitutional Symptoms with Grave Internal Conditions Discovered by Operation.—Dr. Frederick Holme Wiggin reported these cases. The first case was that of a man, forty-three years old, who was presented to him on February 5, 1906, with the history that for the past three years, following his wife's death, he had suffered from constipation, insomnia, and biliary attacks. He also had a chancre on his lip. The insomnia and constipation increased. Cathartic medicine gave him but little relief. The day before Dr. Wiggin saw him he was seized with a violent pain on the right side of the abdomen. His temperature was 99° and pulse 82. Under enemata, castor oil, and tincture of opium he appeared to be somewhat relieved, but the temperature went to 101°. The blood count showed a leucocytosis, and this was found to be increasing. Dr. Lambert was called in consultation and operation was advised. A few days later the symptoms became normal, the pulse falling to 68. Operation was consented to and the cecum was found to be bound down by firm adhesions, which were broken up with much difficulty. The appendix was found to be coated over with thick adhesive material. There was found an abscess containing a dram of pus. The patient made an uneventful recovery, about a month later going to Europe in the enjoyment of good health. Dr. Jeffries examined the tissue and reported inflammatory changes about the appendix which were very extensive, but he was unable to say whether they were specific in character or not. There were no evidences of malignancy or tuberculosis. The man also suffered from arteriosclerosis, the arteries being very hard. If the patient had been left alone no doubt the abscess would have broken through, causing an extensive peritonitis.

The second case reported was that of a woman, thirty-one years old, who for five years past had been troubled with constipation and loss of appetite. She had half a dozen attacks of pain on the right side of the abdomen, etc. The pain was severe and the temperature 99.5°. When Dr. Wiggin saw her the temperature was from 100.2° to 100.4°. Under the use of castor oil her condition improved. The reason for operating was because of the pain and tenderness over the cecum under deep pressure. At operation the appendix was found to be flexed upon itself and a dram of pus was found encapsulated.

The third case reported was that of a man who for three months had a certain amount of pain and nausea every morning. This pain was also very apparent over the cecum when he drove his carriage over a stone or other obstruction. The pulse and temperature were normal. There was a little tenderness over the cecum on pressure. The patient looked ill and an operation was advised. The appendix was found to be thickened and, when opened, five gallstones were discovered in it, one of which had ulcerated nearly through. On the under side of the appendix where the ulceration was there was noted a patch of peritoneal inflammation about the size of a quarter. Dr. Wiggin said that his experience taught him that when a patient presented himself who gave a history of no desire for food, constipation, bilious attacks, with pain or tenderness on pressure over the cecal region, operation should be performed.

The Vitascope—Moving Pictures Showing Certain Manifestations of Nervous Diseases and Illustrating Surgical Operations.—Dr. Cecil MacCoy gave this demonstration. In it he showed moving pictures of characteristic gaits of locomotor ataxia, paralysis agitans, spastic paraplegia, etc. Also hysterical intentional tremors, ankle clonus, muscular dystrophy, chronic chorea, and the *petit mal* form of epilepsy. He also produced pictures of a certain French surgeon amputating at the knee joint, etc.

The Use of Moving Pictures in Teaching Diseases of the Nervous System.—Dr. Edward D. Fisher briefly alluded to the use of the vitascope as an aid in teaching, and thought a great deal was due Dr. MacCoy for bringing this subject before the society, and in such a novel way. Yet he did not think it could take the place of demonstrations on the living subject, provided sufficient material could be obtained for teaching purposes. The vitascope no doubt was a great aid in enabling teachers to show patients with nervous diseases, but he did not believe they would ever do away with the living patients.

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

South Carolina.—At the examination held in June, there were fifty-two applicants; of these, thirty-nine passed and thirteen failed.

North Carolina.—At a recent meeting of the State Board of Medical Examiners, a resolution was adopted to revoke the license of any physician who is addicted to the use of drugs or alcoholic stimulants to such an extent as to incapacitate him for the performance of his duties as a physician.

Missouri reciprocates under certain conditions with Colorado, Delaware, District of Columbia, Indiana, Iowa, Kansas, Kentucky, Maine, Michigan, Minnesota, Nevada, New Jersey, Wisconsin, and Wyoming. Physicians who are licensed in the above-named States can register in Missouri if they received their license prior to March 1, 1901, and had previously graduated from a medical college with four-year requirements. If they received their license since March 1, 1901, in addition to having a diploma from a four-year medical college they must have passed an examination before the State Licensing Board and have obtained an average of at least 75 per cent.

Wisconsin.—At the recent meeting of the State Board of Examiners, sixty-seven licenses to practise were issued to non-resident physicians. The one-year restriction formerly imposed on nonresident doctors has been removed. The following officers were elected: *President,* Dr. W. T. Sarles of Sparta; *Secretary,* Dr. J. V. Stevens of Jefferson. The board resolved that a committee of three be appointed to inquire into charges recently said to have been made, that the State medical examiners are acting in an irregular manner, and that the secretary of the board was acting in the interests of advertising houses.

Whooping Cough	56	11	51	1
Cerebrospinal Meningitis	9	10	0	4
Malarial Fever				
Totals	867	230	817	236

Carcinoma of the Pancreas.—Enrico Grimani tells us that there may be two kinds of foci in the pancreas from which carcinoma may start, the epithelium of the glandular acini and that of the excretory ducts. The last-mentioned structures are the most frequent source of malignant formations. The islands of Langerhans may also be considered as capable of originating cancers. The author has examined the pancreas in a man who died from carcinoma of the pancreas, which enclosed the duct of Wirsung, which had become transformed into a cyst throughout its length; the ductus cholodocus was also affected, while the cystic duct was dilated. The neoplastic alveoli were lined with cylindrical epithelium; the growth was primary in the pancreas, secondary in the liver.—*Archivio per le Scienze Mediche.*

JAPANESE NAVAL SANITATION.*

By BARON K. TAKAKI, M.D., F.R.C.S. Eng., D.C.L.,

TOKYO, JAPAN.

LATE DIRECTOR-GENERAL OF THE MEDICAL DEPARTMENT OF THE IMPERIAL JAPANESE NAVY.

MR. PRESIDENT AND GENTLEMEN:

I am here to-day owing to an invitation from the committee of the Cartwright Lectures. We Japanese feel that it is not only a great honor to me personally but also a great compliment paid to the medical profession of the Japanese Empire, and I thank you all on their behalf for your cordial and friendly feeling towards us.

I was selected as the recipient of your invitation by Professor Kitasato of the Home Department and Education Department because I had some experience with naval hygiene and in forming the preventive measures for diseases occurring among the seamen during my term of office as a naval surgeon between 1872-1893, but as I have no other qualification I am afraid I shall not be able to satisfy your expectations, and I hope you will listen with indulgence to my lectures.

As you all know, previously deaths from diseases during wars had been several times more numerous than those from swords, bullets, and shells. In looking through the history of the last two hundred years we find them in the ratio of 1 to 4. As it is too slow and not worth while to narrate all the details I will not describe them here, but will limit myself to a general history of hygiene in the Japanese Navy, hitherto not well known to the world, *i.e.* from 1872 to 1905, and also to the experiences of our medical officers during the Russo-Japanese War. And as I believe the object of your committee is to hear the present condition of Naval and Military sanitation in the Japanese Empire, I will try to lecture on that subject to my best ability.

I have prepared a table showing various details from 1878 to 1888 and I am now going to explain all the details. From 1888 until the present day there have been no important changes, and if I explain to you the constitution of the Medical Bureau of both Army and Navy, and also the number of cases of illness before and during the Russo-Japanese War, I think you will grasp all the important points of my lectures.

The average number of cases of general disease during 1878, 1879, 1880 was just over 4,327 per thousand, that is, one sailor suffered 4.32 times every year. The death rate averaged 16.34 per thousand and the invalid rate 8.75. The number of patients with kakke was 349.33 per thousand. Those who died from it averaged 7.96, and those invalided, 2.45. Therefore the number of sailors lost through death and made invalids owing to general diseases was 24.09 per thousand and those lost through death and invaliding from kakke, 10.43 per thousand. If we now subtract 10.43 from 24.09 only 13.66 remains. Therefore it was clear that if kakke could be wholly exterminated, the number of losses from illness would decrease to 13.66.

From 1881 to 1883 the number of those was slightly decreased. In 1884 the general aspect of the health of the Navy suddenly changed and the number of hospital cases decreased correspondingly with the decrease in kakke. The number of general diseases was 1,776.27 per thousand, that is, one person became ill 1.77 times a year. Deaths per thousand decreased to 7.98, and invalids to 7.80. The number of kakke cases averaged 127.35 per thousand. Deaths from it decreased to 1.42. Therefore the average of deaths and invalids from general diseases decreased to 15.78 and that of kakke to 1.60. Similarly in 1885 the number of general diseases decreased to 974.85 and deaths to 7.84. Kakke decreased to 5.73 without death. Therefore the number of deaths and invalids decreased to 12.14. In 1886 general diseases per thousand averaged 564.13, deaths 7.43, and kakke 0.35 without death or invaliding. In 1887 general diseases per thousand were 434.22; deaths, 6.04; and invalids, 6.15. In 1888 general diseases per thousand averaged 400.59, deaths, 7.08; and invalids 9.15. Therefore the number of losses through deaths and invalids per thousand in 1884 was 15.78; in 1885, 12.14; in 1886, 12.57; in 1887, 12.19; in 1888, 16.33. If we now compare this period of 5 years with that of the 3 years from 1878 to 1880 we find the marked decrease of general diseases and disappearance of kakke with corresponding decrease in the loss of sailors year by year. These good results must depend upon certain causes, and now I will try to describe various important facts since the establishment of the Naval Medical Bureau in 1872.

Establishment of the Naval Medical Bureau.—The Naval Medical Bureau of the Japanese Empire was established for the first time in 1872. At that time there was not one who had a thorough idea of naval hygiene, because up to that time there was no medical officer in our navy, and other officers thought that the necessity of medical men in the Navy was simply for treating diseases and wounded. Even the medical officers so thought. They never had the slightest idea of doing anything in preventive medicine or in general hygiene. Accordingly the only medical record left from 1872 to 1877 was limited to the description of results of treatment, names of diseases, and names of patients. Between 1876 and 1883 the records gradually began to include facts outside the patients in the naval hospital and also some hygienic affairs. Finally from 1884 the records became more and more complete, giving various tables illustrating the naval hygiene, by the issue of the instructions relating to the duties of the medical officers.

The Education of Naval Medical Officers.—At the time of the establishment of the medical

*Abstract of the Second Cartwright Lecture delivered before the College of Physicians and Surgeons, New York, January 29, 1906.

Bureau in 1872, Dr. Wheeler, attached to the British Legation, was invited by the Naval Hospital to give lectures, both theoretical and practical. In 1872 Dr. William Anderson was specially invited from England to coach the junior medical officers and students. In 1877 16 men qualified and passed out of the school. These were the first graduates. Chief among them were the present Surgeon-Generals Yamamoto, Totsuka, Kimura and Suzuki. However, later on (during my absence in England) the levying of medical students was stopped and the special teacher was discharged. It was then found that as the new medical officers could not understand any foreign language, they could not only not learn anything about naval and military hygiene in foreign lands but they could not follow the progress of medical science in general. Besides, they could not talk and associate with foreign medical officers, and on occasions when they went to foreign ports or lands, they could not find out the sanitary conditions, especially those relative to the endemic and epidemic diseases of those ports or lands.

Again this want of knowledge of foreign languages was very inconvenient when it came to buying food, materials, drinking waters, etc., and thus there was always fear of the invasion of infectious diseases through this channel. Moreover, the foreign language used by the Imperial University in teaching medicine was German, yet that most useful and important to our naval officers was, I thought, English. Finally, as unless those who served in the Navy were able to keep up the general spirit characteristic of the sailors, they could not work hand in hand with the fighting or line officers and would find many inconveniences in conducting the sanitary affairs. I insisted upon reestablishing the naval medical school and raised some students in 1881. Besides the full medical course, English was taught as an extra subject, and by 1894, eighty students in all were graduated as officers. But after that year (in 1893 I retired from active service, was placed in the reserve list, and became a member of the House of Peers) fresh students were not again raised and new medical officers were adopted from among those who had studied in the Imperial University and specially licensed medical schools.

Medical officers were also sent abroad to pursue further study in medicine. In 1872 Drs. S. Ono and K. Yoshida were sent to England, in 1874 Dr. T. Ishigami to England, in 1875 Dr. K. Takaki to England, and in 1878 Dr. A. Saneyoshi to England. Since then one or two medical officers were sent each year to Europe, chiefly to England and Germany.

The Education of Nurses.—Nurses were educated and taught the subjects necessary to their calling in the hospital at each naval station. I entered the Navy in 1872 and began to treat the sick and wounded. What at once attracted my notice was the large number of kakke patients and the numerous deaths resulting from it. And as this disease truly played havoc with the health of our Navy and killed many so as to greatly reduce our fighting strength, I directed all my efforts toward finding its cause and treatment. By doing so, I meant to prevent the outbreak of this disease and provide against unforeseen danger through ill-health in time of crisis of our Empire. In pursuing this purpose I met with many difficulties and passed through years of hard work.

The first time I heard of the fearful nature of kakke was forty-four years ago. At that time guards were despatched from several Daimios to Kyoto to act as protectors of the Imperial Palace, and my father being one of them stayed there for over a year. On his return, he told me of the disease called kakke which killed many of these men. They attributed the cause to food, and called a provision box the "kakke box."

Later, in 1868, that is, in the year of the Meiji Revolution, I served for eight months in the army of Prince Shimadzu but did not see any cases of kakke. As said before, I entered the Navy in 1872 and began then to treat kakke patients for the first time. Up to May, 1875, I had seen several hundreds of kakke cases at the Naval Hospital. In summer several acute cases appeared daily. Often five or six cases had to be treated at the same time, and the house officers had to work very hard through the day and night. At that time, the kakke patients constituted three-fourths of the whole number of patients. The treatment adopted was purgatives and digitalis for edema, palpitation, etc.; strichnine, iron, etc., for numbness and paralysis; tincture of aconite, for hypersensibility of the muscles; purgatives and venesection for acute cases. This treatment was general, and there was no definite opinion as regards the food.

Conditions being such, it became my fixed desire to discover the cause and treatment of kakke. But I thought that with my insufficient knowledge of medical science, I could not possibly discover them, and from then on the desire to go abroad in order to fit me for attaining my object never left my thoughts even for a moment. At last in June, 1875, the desire was fulfilled and I started for England. I reached London in July and entered St. Thomas' Hospital Medical School in October. After staying there for over five years, I returned to Japan in November, 1880, and was made the director of the Tokyo Naval Hospital in December. Thus, I got the opportunity to treat kakke patients again. The general conditions on my return were exactly the same as before I went to England, and with subsequent increase of sailors, more kakke cases appeared. At times when the disease was in full force we found the hospital too small and often had to use neighboring temples. Moreover, acute cases were many and the medical officers had a very busy and hard time. Such conditions struck my heart cold whenever I thought of the future of our empire, for unless we could discover the cause and treatment of kakke, our Navy would be of no use in time of need.

As a first step toward the cause and cure of this disease, I began to note the localities and seasons and to examine sailors in ships, barracks, etc., and I obtained the following facts. (1) Kakke occurred mostly from the end of spring to summer, but it was not limited to the warm season, sometimes occurring during the severe cold of winter. (2) It varied in different ships, barracks, etc. (3) Even in the same ship, it appeared in some stations, but not in others. (4) Within the same building and with the same clothes it sometimes occurred and at other times it did not. (5) I discovered that although clothes, food, living, etc. were not quite the same in all stations, yet they were almost similar.

With these facts I could not easily discover the cause, and I went on with further investigations with the following results: (1) As regards the class of patients in general, I found that sailors, soldiers, policemen, students, shop-boys, etc., were those who most suffered. The upper class also had but more rarely become affected. (2) The people living in the same place suffered unequally, that is, some suffered and others not. (3) Although it occurred mostly in large cities, like Tokyo, Osaka and Kyoto, yet it sometimes appeared in other cities and towns also.

Thus with such results and without discovering

the cause of kakke the time quickly passed to the year 1881. In February of the year 1882 I was appointed the Vice-Director of the Naval Medical Bureau. About that time it was found to be necessary to provide an extra medical officer besides the usual number for training ships going for long voyages with cadets when they had finished the Naval College course, because kakke used to occur abundantly during a voyage.

In 1882 there was a crisis with Corea and three warships were sent to (Chemulpo) Ninsen and Saibutsu Bay. They stayed there only forty days, but owing to the shortness of hands caused by the prevalence of kakke among the sailors, the officers felt quite unfit for battle. (For example, on board *Hiyei* out of 330, 195 suffered). It was a very anxious time for those in position, because if those three ships had been captured by China at that time, we should have been unable to cope with the North China Squadron. As a consequence I handed to the chief of Naval Medical Bureau on the 24th of June, 1882, a memorandum describing the facts.

Following this, in August, 1882, H.I.M.S. *Fuso,* in spite of anchoring off Shinagawa Bay had to send half of its crew ashore for treatment for kakke.

Continuing still further, I examined the reports of the Tokyo and the Yokohama Naval Hospitals for 1881 and discovered that three-fourths of the patients were suffering from kakke.

In 1883 I got an order from the Minister of the Navy to permit me to examine the hygienic conditions of ships, barracks, schools, etc., belonging to the Navy. I found that although the working hours, clothing, dwelling houses, etc., were similar everywhere, yet in food there was a great deal of difference. So I now asked the head of each section department to send me in the reports describing the details of food taken three times daily for a week. From this I discovered the following facts: (1) Albuminates contained in the food were not sufficient to make up for the amount of albuminates discharged from the body. (2) On the contrary, the food contained too much carbohydrate. If we now look into the table recognized by the scientific world showing the comparative amounts of nitrogen and carbon discharged daily by a fair sized adult, we will see that carbon 310 grams and nitrogen 20 grams, *i.e.* N. 1 to C. 15.5. (3) The food taken by our sailors showed N., to C. 18 to 32. (4) The greater the difference in these proportions the more kakke occurred; and the less the difference, the less kakke.

After obtaining these important facts I came to the conclusions that: (1) Kakke is caused by the disproportion of nitrogenous and nonnitrogenous element (C. and N.) in the food; that is, the amount of the nitrogenous was insufficient to make up the loss and that of nonnitrogenous excess. (2) The symptoms of kakke patients are really due to these causes, and the good results obtained by purgatives are due to their powers in getting rid of the superabundant carbohydrates. (3) The changes occurring in nerves, muscles, etc., are due to their inability to repair the waste tissues, and consequently to perform their physiological functions; while superfluous carbohydrates act as unuseful elements interfering with nutritive process.

In October, 1882, I offered a proposal to the late Count Kawamura, the chief purpose of which was to change the old dietary system. When this proposal was put forward before a meeting there was a good deal of opposition. They said that the change was too radical and instanced the great disturbance caused by the change of diet in the Italian Navy some years before. They also called attention to the new system of fixing the amount of food by quality and quantity instead of by monetary value. In spite of difficulties caused by this opposition, my opinion finally prevailed, and the new system was adopted. But, as we required a few months longer in order to examine and fix the quality and quantity of food to be given, and as even some medical officers were secretly in opposition, I took this occasion to try the new system on a certain number of patients in the Tokyo Naval Hospital, comparing the result with that of the old system.

The experiments were continued for a period of four weeks. The average increase of weight of the five patients on the new diet was 160 momme,* that of the five patients on the old diet was 170 momme. Of the patients on the new diet all were discharged cured; of those on the old diet four were discharged cured, one became tuberculous.

In December of the same year, in order to ascertain the amount of food suitable for officers and men, a special body weight table was published and made to be reported on a certain fixed date yearly. By this means we got a comparative scale of bodily weight noted once every month and continued for five years from 1884 to 1888.

This table showed that the bodily weight was highest during the months of February, March, and April and lowest in August and September. Therefore after 1889 the weights were taken only in March and September every year.

During ten years from 1884 to 1893 there was more or less difference yearly, but, taken as a whole, the weight has increased nearly eight pounds. From 1894 to 1903, for ten years, there was not much change in weight, and I think that shows the sufficiency of food supplied. During the former ten years the number of general diseases decreased in accordance with the yearly increase of weight. The last ten years showed no change in weight and diseases. This shows that there is more or less increase or decrease even in a healthy body during twelve months, and that these changes are physiological and have no relation to health.

On September 26, 1883, I for the first time spoke on the cause of kakke before the meeting of the Society of Hygiene, and published my opinion that it was due to a disproportion in the carbon and nitrogen content.

On October 5, 1883, I was promoted to be director of Medical Bureau. Soon afterward I asked the Minister of the Navy to have a special committee of investigation on the cause of occurrence of an almost unprecedented number of cases of kakke on board the training-ship *Riujo,* which left Shinagawa on December 19, 1882, and returned to Shinagawa on October 15, 1883, after voyaging through New Zealand, South America and Hawaii, spending 271 days.

My proposal was adopted and a special committee consisting of the following members was formed: Rear-Admiral Maki, chairman; Surgeon-General Takaki, Captain Isobe, Commander Kunitomo, Fleet-Surgeon Kagami, Fleet-Surgeon Toyozumi, Paymaster Ijichi, Paymaster Kurihara, Secretary Iwamura, Lieutenant Serada, clerks—Matsumura, Sakamoto, Mishina.

The first meeting of the committee was held on November 12, 1883. Chairman Maki explained the object of this committee and I was appointed chief of the investigation board. After this, meetings were held on Monday, Tuesday, Wednesday, Thursday and Friday every week up to April 11, 1884, and altogether the committee met seventy-nine times.

*One momme is the equivalent of 3.8 grams Troy.

As a result, I, with the assistance of Staff-Surgeon Toyozumi, compiled ten chapters entitled: (1) Patients, (2) Clothes, (3) Bedding, (4) Food, (5) Drink, (6) Housing, (7) Labor, (8) Rest, (9) Voyage, (10) Anchorage, (11) Weather and Climate, and (12) Conclusion.

Besides, we made up 6 tables on diseases, 32 tables on food, 1 each on drink, climate, weather, and temperature, and also tables on the food supplied daily to petty officers, sailors, students, gunroom officers, and officers. Finally the committee met to discuss the results of investigations on February 12, 1885.

In November, 1883, I was informed of the sailing of the training ship *Tsukuba* in a short time, and at once planned to utilize this opportunity to vindicate the new system of reformed dietary by making *Tsukuba* voyage through the same route as *Ryujo*. So in spite of the proposal of October, 1882, I demanded the immediate practical application of the new diet before the sailing of *Tsukuba* on November 24, and in consequence, the Minister of the Navy issued the order of the change of diet throughout the Navy on November 29. Again on November 26, 1883, I proposed the necessity of the Medical Bureau having the reports of food supplied in ships, barracks, schools, etc., every month, and in the following December the minister ordered its application. These reports have continued until the present day.

On November 29, 1883, I had the honor of being presented to His Imperial Majesty at Akasaka Palace, and on this occasion explained my views as regards the cause and prevention of kakke. There were three chief reasons for my representation: (1) The fighting strength of the Army and Navy engaged in the protection of our empire is greatly weakened through deaths and invalids caused by kakke, and the latter gives a great anxiety to those in position to look after the hygiene of both Navy and Army. (2) Many students with bright prospects may have to stop their studies or may die from this disease. That would be a great misfortune for the future of our empire. (3) If we discover the cause and preventive measures for this disease, it will be recognized as a great forward movement.

The Methods for Investigating the Cause of Kakke.—(1) As we cannot discover the true origin of kakke in spite of examination of symptoms, etc., we must use some other means. (2) In order to examine the food necessary for nourishing the human body, it is important to know the comparative scale of nutritive elements, that is, albuminates, fat, carbohydrates, and salts, and of C. and N. (3) In examining the suitability of nutritive elements in food taken by those suffering from kakke, it is found that the proportion is not proper. (4) The causes of this disease are due to the loss of equilibrium in the proportion of nutritive elements and also to the deficiency of a certain element; that is, the compounding of food is not properly done. (5) The occurrence of kakke due to the deficiency of a definite element, that is, albuminate, is shown with the examples of the long voyages of *Asama, Tsukuba, Ryujo,* etc. The disease does not occur if the food is well supplied. (*a*) It does not occur among men having a sufficient supply of food or among officers. (*b*) In voyages with long stoppages at ports and short sailings. (*c*) From 1882 to 1883, when *Ryujo* went for long voyages, the disease disappeared completely as soon as she arrived at Hawaii and was supplied with fresh eating materials. (6) High temperature, moisture, marshy air, crowding, hard labors, nervous exertion, coarse food, etc., cannot be considered the chief causes of kakke, because if they are the causes both Europeans and Americans ought to suffer, but on the contrary, they do not. (7) In considering them from both theoretical and practical points, they seem quite reasonable; therefore, the true cause of kakke lies in the wrong method of food supply. Now that the monetary method of giving food has an important relation, and as this method is considered wrong, it ought at once to be changed so as to make our fighters healthy and unconquerable.

In December, 1883, instead of the very simple rules of the former time, I compiled a new book of instructions consisting of seventy-seven articles and twenty-two blank forms, and had it used throughout the Navy by the approval of Minister of the Navy. This book, since several times revised, is still being used.

On January 15, 1884, Jungi Kawamura, Minister of the Navy, issued the following notification to the Navy: "It is hereby ordered that the following regulations in regard to the supply of food to the petty officers and men in ships and barracks shall be observed from February 1, 1884.

Regulations in Regard to the Supply of Food to the Petty Officers and Men in Ships and Barracks.

Article I. The food of petty officers and men in ships and barracks shall be under the control of the principal officer under whom they are serving, and the articles of food shall be bought with the money allotted for the purpose, and supplied to them.

Article II. The articles of food shall be as follows: Rice, bread, beef (fresh or preserved), salted beef, salted pork, fowls or eggs, fish, *miso,** shoyu (sauce), vegetables (potatoes, carrots, radishes, cabbages, and onions), beans, wheat, flour, tea, fats and oils (suet or lard, butter, olive oil, oil of the sesamum orientalis), sugar (and starch), milk, vinegar, spices, alcoholic liquors, salt, pickles.

Article III. The articles of food shall be bought by the paymaster by order of the officer in command, and they shall be given out after being examined by the surgeon.

Article IV. A record of the articles of food shall be kept by the paymaster, which record shall frequently be examined by the officer in command.

Article V. If the preserved articles of food are found to be in bad condition, the matter shall be reported by the paymaster to the officer in command, who, in turn, shall order the surgeon or other officer to examine them and shall report the matter to the Minister of the Navy Department through the chiefs of different departments.

In 1883, after my proposal to reform the food system on November 26, I made a great effort to have the *Tsukuba* go over the same route as the *Ryujo*. There was opposition to this from various points and the permission could not be obtained easily, but in the end, after much discussion, all difficulties were overcome except that of expense. So, with the knowledge of the Minister of the Navy, I consulted Hakubun Ito, member of the Imperial household, and Seigi Matsugata, Minister of Finance, and finally reached my goal by the special allowance of 60,000 yen from the treasury.

Before the sailing of the *Tsukuba* a special committee for investigation was put on board, and consisted of Captain S. Arichi, Lieutenant Y. Matsumura, Surgeon T. Aoki, and Paymaster N. Kataoka.

The food supply was ordered according to the new system. The vessel sailed on February 2 and returned to Shinagawa on November 16. The result obtained was good, comparing it with that of the *Ryujo*.

*A kind of sauce made of beans, barley, and salt.

When the good report at the end of September of the year ("no kakke") of the experimental voyage of the *Tsukuba* became known, the principal men (Minister excepted) in the Navy for the first time began to support me in my fixed purpose. They said that they had always opposed me in their hearts and only obeyed the new regulation because they were ordered by the Minister, but they must give in now with such powerful practical proofs.

In January, 1885, on looking through the reports of 1884, I was greatly satisfied with the results. The number of general diseases was nearly halved and that of kakke considerably decreased with no death. With such results I began to make public more and more my views on the preventive measures for kakke.

On February 2, 1885, Baron Ishiguro, Surgeon-General of the Army, who is my close friend, published a book on kakke. He had studied the cause and preventive measures for some years and came to the conclusion that the chief cause of kakke is the unhealthy and unwholesome air in rooms, and that the disease can be prevented with the supply of fresh air.

On February 13, 1885, I made a new proposal for using barley and rice equally instead of rice alone, and of having this adopted from March 1, as the season of kakke was approaching, under the following rules: From March 1 to March 15, only once, at breakfast; from March 16 to 31, twice a day, morning and evening; after April 1, at every meal. I did this for the following reason:

Although the number of cases of kakke decreased considerably (almost to half of the year before), and deaths in the Navy had become so few, almost unprecedented since the establishment of our Navy, owing to the new food regulations of February, 1884, yet the disease had not yet disappeared completely, and we must make further efforts to exterminate it. Then I thought of the plan of using barley instead of bread alone, as the men could eat the former better than the bread. From this I expected better results. The Minister of the Navy ordered the addition of the word "barley" amongst the articles of food, and its practical application on December 21 throughout the whole Navy. As I saw uneasiness arising among the Navy officers and men owing to the change, and as, moreover, I wanted to report the full results of the investigation on the voyage of the *Ryujo* and also wanted to tell the purpose of this new change, I, with the approval of the Minister of the Navy, delivered the following address at the Naval Club on February 25:

"All of the gentlemen here present will remember the orders, C. No. 2,743 (2), issued on the 29th of November, 1883, and C. No. 7, issued in January, 1884, by which regulations regarding food were made for the first time. By last year's experience we have found that most of the men dislike meat as well as bread, and we do not know what we shall do next. But if we leave the matter to their own choice, we shall certainly have a great many cases of kakke, as has hitherto been the case, especially as more than 1,000 new men have been enlisted this year. Now, there is nothing better than barley food for preventing kakke. As, however, barley is coarse in appearance, we are afraid that some of the men who do not understand the object of the improvement in the scale of diet will feel dissatisfied. We consequently wish to speak about the preventive measures to be adopted against kakke and to take this opportunity of reporting the result of the examination into kakke on board the *Ryujo*.

"That kakke can be prevented by an improvement in the scale of diet has been deduced from scientific reasoning, and has been proved by experience in our Navy, and for a long time we were planning such preventive measures. Fortunately, G. No. 2,743 (2) was issued on the 29th of November, 1883, directing that nutritious food should be given as far as possible, to which followed the regulations in regard to the supply of food, which were issued with C. No. 7, in January, 1884. According to these regulations, the Medical Bureau drew up tables showing the proper amount of food for healthy men and invalids, and distributed these to vessels, barracks, and hospitals, thus trying to insure the health of the men. As, however, we had expected, these suggestions often could not be carried out, especially in the case of newly enlisted men, who not only dislike bread, but cannot take a proper amount of meat. If things are left in such a condition, there is no doubt, from recent experience, that we shall again have a great many cases of kakke this year, in spite of the favorable result shown in the decrease of cases of kakke which was obtained in the year which followed the improvement in the scale of diet. This is why we decided to give the barley food. We believe that the majority of the men in our Navy have been used to take barley food from their childhood, so that in reality they can eat it, although they show their dissatisfaction at it after becoming accustomed to the rice given to them since they entered the Navy. It is accordingly considered that the best preventive measure, at present, against kakke, will be to give barley, which it was directed should be given to the Navy in general from the month of March by the order of the 21st inst. If this order is carried out strictly, we are sure to find no case of kakke in our Navy. We consequently ask you, gentlemen, that you will kindly help us in the work of prevention, for the good of our country, according to the order just given."

On March 19, 1885, I obtained the honor of an interview with His Majesty the Emperor and presented the reports of the following items: (1) The results of kakke investigation on board the *Ryujo*. (2) The decrease of kakke from the gradual improvement of diet since January 15, 1884. (3) A great probability of exterminating the disease from the Navy in a few years.

An March 28, 1885, I for a second time spoke on the preventive measures of kakke before the meeting of the Hygienic Society of Japan; the chief items of this address were: (1) The report of the investigating committee placed on board the training-ship *Ryujo* during its voyage in 1883. (2) The report of the experimental voyage of the *Tsukuba* in 1883. (3) The results obtained through the examination of food supplied in 1883, that is, a very small quantity of nitrogenous food as against the large amount of carbohydrates, the proportion being nitrogen 1 to 28 of carbon. In addition, the occurrence of numerous cases of kakke and general diseases during that year. (4) The good results obtained by improved diet since 1884 and the difference brought about in the proportion of nitrogen and carbon by various changes in the proportion of diet.

Soon after my speech, Toyosaku Murata, a member of the Hygienic Society, wrote a long letter to a daily newspaper against my opinion.

On April 6, 1885, Prof. Ogata of the Imperial University and Home Department reported to Count Yamagata, Minister of Home Affairs, the discovery of the kakke bacillus. In this he said that he found a short blunt-pointed bacillus in the cardiac muscle, liver, fats, kidneys, spinal cord, etc., and that he had

confirmed it by cultures. He utilized rats, rabbits, and monkeys for experiments. He published a second report afterwards, but after all it came to nothing.

On the 18th of the same month, Kenji Osawa, member of the Hygienic Society, in a long speech attacked my opinion as regards the choice of diet, especially of barley and beans, but about a year afterwards he told me that he had been wrong.

Similar attacks appeared in speeches and writings continuously up to the end of 1887, but I kept complete silence, as I wanted to reply by practical results. Luckily for me, the later results showed gradual improvement, that is, forty-one cases of kakke in 1885, only three in 1886, and none in 1887, and enabled me to retaliate by their publication.

About this time, Moriharu Miura of the Imperial University published a new opinion regarding the cause of kakke. He attributed it to the poisons of blue fishes, because he said that the symptoms simulated mineral poisoning, as by lead, and that since the improved system of diet in 1884 the fish supply had gradually decreased, especially from 1885 to 1889. He made practical applications of his idea to some regiments, but as we have heard nothing about it since, it must be accounted as a non-success.

On August 24, 1885, I made a proposal to change bread and biscuit for a proportionate amount of barley and rice which had been supplied since March of that year, because I recognized its necessity owing to the great difficulty in making bread experienced during rough weather even in time of peace. In November of that year my proposal was taken up and its application was at once ordered so as to make the sailors accustomed to their use.

Experiments on Dogs. — Finally, besides arranging and investigating as described, I had thought of experimenting on dogs, and in September, 1884, commenced my experiments. The results obtained were as follows:

First Experiment.—I took six dogs at the beginning of September, 1884, and separated them into two groups, A and B, and brought them up, giving to each differently combined food materials. The dogs in group A received rice and vegetables. They all gained in weight, but all died. In group B. the dogs received beef in addition to rice and vegetables. They gained less in weight than the dogs in group A, but all lived and were healthy. The increase in weight of three dogs of A group, when compared with the weight first taken, showed an increase of 2,905 momme, but all the dogs died. The total increase in weight of the three dogs of B group, when compared with the weight first taken, was only 1,430 momme, but all were still alive and healthy. Therefore, it is not always reasonable to take the increase of bodily weight as a positive proof of health.

The above results are proofs of the difference in the physiological constitution of animal life produced by the consumption of different combinations of food. It was also shown by the quantity of feces passed, that the digestion and absorption are not the same in each dog, though the same combination of food is given to each. Further, the quantity of excrements of those dogs which took the food mixed with meat is less than that of the dogs which took no meat.

Second Experiment.—This experiment was commenced on September 1, 1885, and completed on November 30, 1886. At this time, as at first, six dogs were used and separated into two groups, A and B, and differently combined foods given to each group. The principal articles of food given to A group were rice and sweet potatoes, and that given to B. group consisted of boiled barley, beans (soja Hispidia) and sweet potatoes. The other articles of food given to each group were the same and the quantity of these articles was determined according to the weight of each dog. Two of the three dogs in group A died; those in B group all lived.

The result of the two experiments was that of those six dogs to which rice was given as the principal food, in spite of an increase in weight, all but one died before the expiration of the experiment. The increase in weight of six dogs to which barley, beef, and beans were given as their principal food, was not so conspicuous as in that of the other group, but every one of them was healthy and very active both mentally and bodily.

Therefore, although these experiments seem to be very crude, yet the results certainly prove that the variety of food consumed and its combination have direct influence upon the health of animal life.

It is not quite proper to conclude that the causes which affect the health and development of man will produce in some ways the same results as in dogs, but I have no doubt that the health of man is greatly influenced by the variety and combination of food consumed as well.

By the beginning of 1890, the reformed diet was crowned with a complete success, and not only kakke was wholly exterminated, but also the general diseases became greatly decreased.

In the same year the Imperial ordinance for reformed diet was issued, and thus my original object was obtained.

All through these years of hardships I tried to explain my purpose to others by comparing the food to gunpowder. I said that the former is the primary force of the human body as is the powder in the gun; so it is just as important to select the food suitable for sailors as the powder for guns and rifles.

In former times the food was supplied according to the monetary system without any regard for quality or quantity. Therefore, when the price of food articles was high they could not get sufficient nutrition for the maintenance of health, although they were able to get more when it was low. As a consequence, the distribution of food was unequal at times, and although the sailors could stand any hardship at one time, yet they could not at other times, owing to the want of food. Such a state of things is a serious danger for the country in time of need. The gunpowder is supplied with a definite quantity of the best quality without considering the amount of expense. This is what I wish to have in regard to the supply of food. By doing so we can preserve the equal supply of suitable food at all times, and also keep the officers and men in good health, so that they can bear hardships both in peace and war. In 1890, as the success of the reformed diet became positive, the particulars concerning the preventive measures taken for kakke were compiled into a book, and presented to the Minister of the Navy.

As the result of the reformed diet with the improvement of the Naval hygiene, during six years, from 1884 to 1889, the amount of expense saved from the waste amounted to 1,232,416½ yen. On October 16, 1890, I for the third time had the honor of audience of His Majesty the Emperor, and represented the following facts: (1) As I foretold on the occasion of the presentation to His Majesty in 1885, kakke had now been completely exterminated from the Imperial Navy. (2) The present condition of the health of the Imperial Navy and the economic influence of the improved diet were

due to the Naval expenditure. (3) The fear of the inability of the Naval officers and men for hardships in time of need had now gone. (4) The general tendency of the increase of kakke among students and others without any regard for profession had now vanished. (5) The appearance of kakke all over the country and its tendency to increase seemed to have its origin in the reformed land-tax of Meiji 6 (1873). Since that time the habit of eating rice as the chief food settled upon the remote districts, and, besides, owing to the general tendency throughout the country to raise mulberry leaves, the production of rice and other cereals markedly decreased. In consequence, the vegetable albuminates contained in food necessary for bodily nutrition decreased, while on the contrary, the amount of carbohydrates comparatively increased, thus causing the increase of the disease.

On thinking over my past experiences I cannot hesitate to declare that the present improved condition of the Imperial Japanese Naval hygiene was due to having had an able man at the head of the Navy, and also to the education of medical officers. Because, if we had not such a man at the head, new suggestions would not have been taken up, or if the medical officers were not thoroughly educated, they could not have succeeded in the task of the preventive measures. The success of the new system and the attaining of my long-cherished desire were accomplished owing to the late Count Jungi Kawamura, who was the Minister of the Navy when I was made the Chief Director of the Medical Bureau. When I first took up the official duty as the Director of the Medical Bureau, I told the Count that if he would give me full power to execute whatever I deemed necessary in order to keep up the health of the Naval officers and men so as to make them fit for any duty, I would never say a word against his plans in other branches (education, training, duties of officers and men). He then answered, "All right." So that whenever I wanted to try any new plan, he always supported me in carrying it out as long as circumstances allowed.

In order to maintain the health and efficiency of the men, I firmly believe it to be of permanent importance to have the following facts in constant observation: A careful selection of men at the time of enlistment and the maintenance of their health are absolutely essential to fulfill the purposes of the Army and Navy.

To fulfill these objects there must be an organization in which the medical officers and nurses must be properly educated so as to fit them for their duties, and the officers and men of other branches must be taught elementary physiology and hygiene. Accordingly, in Japan, elementary physiology and hygiene are taught to cadets and officers, in addition to the subjects special to themselves, at both the Naval College and the Academy. Petty officers and men are also instructed by medical officers attached to various departments.

The Medical Bureau of the Imperial Japanese Navy is constituted as follows:

I. The Medical Bureau is one of five departments of the Navy and has the following officers: Director, Surgeon-Admiral, 1; Surgeon-Captain, 1; members, surgeons, surgeon-lieutenant, and pharmacist, 4; clerks, 3.

The Bureau governs the following: (1) The medical administration, hygiene, pension, and physical examination of men to be enlisted. (2) Transactions concerning hospitals and materials for treatment. (3) Education of the medical officers and pharmacists.

II. *Education of Naval Medical Officers.*—In the medical school under the control of the director of Medical Bureau, the officers are taught advanced subjects. Not only that, but the newly-appointed officers and probational surgeons and pharmacists are instructed in subjects necessary for their future positions. Besides, the hygienic experiments for clothing, food, etc., are here conducted.

The medical school has the following officers: Dean, aide-de-camp, professors, and treasurer. The scholars are divided into three classes: (1) official; (2) special; (3) training.

The first class consists of officers selected by the Minister of the Navy.

The second class are selected by the Minister of the Navy from commander-surgeon and surgeon-lieutenants (served more than three years) wishing to pursue their studies further.

The third class contains the newly-appointed officers and probational surgeons and pharmacists.

A special class may be found from among medical officers and pharmacists according to the necessity.

The dean makes the rules concerning instructions, etc., according to the school regulations, and puts them into effect after getting an approval of the director of the Naval Medical Bureau.

At the end of every year, the results of examinations and investigations made at the school are fully considered by the dean, who has to forward them to the Director of the Medical Bureau with his remarks.

The dean presides over the meeting consisting of professors and teachers called to discuss the progress of the science and plans for future teaching, and he has to report its results to the Director of the Medical Bureau.

Again, the results of sanitary investigations on clothes, food, etc., are also reported to the Director.

The term of both "official" and "special" classes is one year. Of the "training" class, half a year for the newly-appointed officers, six months each in school and hospital, making up one year for the probational surgeons and pharmacists. A special teacher is nominated by the dean for the "special" class, in order to direct investigations, and at the end of the term each of the classes has to describe and report the results of the investigations made to the dean.

The members of the first and second classes live outside, but those of the third class in the school. Finally, when the Director of the Medical Bureau sees the necessity of forming a special class, he has to fix the number, subjects, and terms, and to represent them to the Minister of the Navy. The latter will then order the formation of the class.

The subjects for an official class are as follows:

(1) Naval Hygiene: Construction of ships, ventilation, drinking water, diet, disinfection, prevention of infectious diseases, etc., clothes.

(2) Geographical Diseases: Endemic and epidemic diseases of other countries, especially along the coast of each.

(3) Military Surgery: Varieties, characters, complications, treatment, etc., of the wounds occurring in sea and land battles.

(4) Military Medicine: Diagnosis, treatment, and practical clinical training.

(5) Physico-Chemical Examinations: Practical methods for examining food articles and others concerning sanitary investigations and clinical diagnosis.

(6) Bacteriology: Methods for bacteriological investigation, necessary for pathogenic bacteria.

(7) Pathological Anatomy: Pathology, both theoretical and practical.

Extra subjects: Foreign languages (English or German or French), practical study of surgical operations, practical surgical anatomy, ophthalmology, diseases of ear, nose, and throat, medical jurisprudence, dentistry, photography, medical electricity.

The members of the "special" class are allowed to pursue their studies in advanced subjects according to their wishes.

The subjects for the "training" class for the probational surgeons are:

(1) Naval Hygiene: General idea of ship construction and hygiene in special reference to the Navy.

(2) Geographical Diseases: General idea of endemic and epidemic diseases of different countries.

(3) Military Surgery: General pathology of gunshot wounds, first aid, conveyance of the wounded.

(4) Methods for examining food articles: Practice of physico-chemical investigation.

(5) Pathological Anatomy: General pathology, both theoretical and practical.

(6) Bacteriology: General bacteriology and methods for practical investigation.

(7) Clinical practice with patients, both medical and surgical.

(8) Foreign Language: (English conversation.)

Extra subjects: Regulation of the Navy.

The probational pharmacists are taught with the subjects necessary for their duties. The object of the special class is to teach certain special subjects in the shortest possible time.

The Regulations for the Education of Nurses.—The subjects are: Anatomy, physiology, pharmacy, bandaging, nursing, methods for the conveyance of patients. All the subjects except the last are taught in the Naval Hospital. Instruction in the last is given in the Naval Barrack. As bandaging and nursing are their most important duties, the nurses are especially instructed in these subjects.

Extra subjects are: Reading, penmanship, composition, arithmetic, gymnastics, care and use of firearms; naval nomenclature, names of the parts of ships and their belongings; rowing of Japanese and foreign boats; methods of transmitting commands; swimming, etc. The period of education occupies eight months.

Higher Education of Nurses.—The training schools for post-graduate instruction in nursing are established within Naval hospitals, and one director and several teachers are attached to each. They teach two different classes of nurses selected from different parts of the Navy. The terms begin on February 20 and on September 1, and end on July 20 and February 10 respectively every year.

The following are the subjects for two classes:

B Class:

1. Disinfection (20 lectures of an hour each.)

2. First aid (lectures and practices, 30 hours). Fainting, asphyxia, drowning, stranguary, inhalation of poisonous gas, poisoning, visceral hemorrhage, retention of urine, burns and scalds, chilblains, hemostatic methods, bites, etc.

3. Bandaging (lectures and practices, 30 hours); materials, making, sterilization, applications, plaster-of-Paris and splints, etc.

4. "Carrying the wounded" (lectures and practices, 20 hours); manual and mechanical conveyances.

5. Management of medical stores (lectures and practices, 5 hours).

6. Practical pharmacy at the dispensary.

7. Nursing in the wards.

The time for lectures and practice is 90 hours (5 hours every week.) The students receive instruction in the wards from the medical officers, in dispensary and medical stores from the pharmacists, and assist the regular members of each.

A Class:

1. General outline of infective diseases affecting the wounds (lectures, 15 hours).

2. Antiseptic dressing (lectures and practices, 25 hours); definition of antiseptic treatment, preparation and use of antiseptic bandages, preparation of sterilized water and applications, preparations for operation, disinfection of operating theater, patient, clothes, instruments, etc., important points during and after operation.

3. Aseptic treatment (lectures and practices, 10 hours); definition, preparation and application of aseptic bandages.

4. Management of Infectious Diseases (lectures, 25 hours); varieties, causes of each, nursing, examination of discharges.

5. Methods for examining the drinking water (qualitative analysis).

6. Pharmacy (practical) in the dispensary.

7. General nursing in the wards.

The hours for lectures and practice are 90 (5 hours every week). The students receive instructions in the wards and operating room from the medical officers and assist in the duties of the regular members of each.

Remarks:

The death rate in the Navy was, as is seen in the table following, 51 per cent., and that in the Army was 28 per cent., thus showing that the rate of instant death is much larger in the Navy. This is no doubt due to the more powerful projectiles used in the Navy causing much damage by their explosions.

All the wounded were treated aseptically. Operations were avoided as much as possible because we found that conservative surgery is most efficient.

In our Army and Navy also before the battle commences, we are in the habit of putting on new clothes after cleansing the body thoroughly as a matter of self-respect, and also this is useful as a preventive method against introduction of any septic matter from the outside when injured or wounded.

REMARKS ON BANTI'S DISEASE (SPLENOMEGALIA AND CIRRHOSIS OF THE LIVER).*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

In 1894 Banti[1] described four cases of splenomegalia, anemia, cirrhosis of the liver, and ascites, which ended fatally and came to an autopsy. From observations made on these and six other similar cases Banti described the clinical picture of the disease, which is at present universally known by his name. The essential part is a combination of splenomegalia, anemia, cirrhosis of the liver, and finally ascites. Although all these clinical manifestations were known, it was formerly customary to classify them according to the predominance of one or the other symptoms. It was Banti who first pointed out the relation of these various phenomena to each other.

*Read before the American Gastroenterological Association on June 4, 1906, at Boston, Mass.

According to Banti the disease has three stages: The preascitic or anemic, the intermediary, and the ascitic stage. Symptoms of the first stage are anemia and swelling of the spleen; increasing weakness, pallor of the mucous membranes, and dyspnea on exertion follow. Sometimes epistaxis occurs, or if there is severe anemia a transitory edema of the malleoli and an irregular intermittent fever result.

The blood shows diminution of the number of red blood corpuscles, a still more marked decrease in the amount of hemoglobin and poikilocytosis. The leucocytes are normal in every respect.

The anemia sometimes grows better, sometimes worse; it is amenable to rational treatment (arsenic, iron).

The swelling of the spleen develops slowly. When the patient consults a physician it has usually reached such dimensions that it represents a large tumor. It retains in general the rounded shape of the spleen, but is of a firmer consistency, and usually projects into the left abdominal cavity to a point somewhere between the navel and iliac crest. Banti thinks there is no doubt at all that the swelling of the spleen precedes the anemia. Liver and kidneys are normal. The first or preascitic stage lasts from one to four and a half years.

Now comes the second or transitional stage. At this time the urine is passed less frequently, and dyspeptic symptoms, like diarrhea, hemorrhoids, etc., arise. This stage is relatively short and lasts only a few months.

The third or ascitic stage begins with distention of the abdomen and ascites slowly develops. The fluid is never absorbed. Even after puncture the fluid will reaccumulate again very soon. At this time a decrease in size of the liver dullness can be demonstrated, the spleen remaining unchanged. The urine is diminished in quantity, concentrated, contains much urobilin, but no bile pigments, no albumin, and no sugar. The skin is of a somewhat darker hue and the conjunctiva somewhat icteric.

The signs of anemia slowly increase, and slight rises of temperature in the evening occur. The patient becomes progressively weaker, and unless some other disease carries him off he dies from exhaustion.

The last stage is relatively short, lasting generally only a few months, at the highest seven to eight.

Pathologically a large amount of connective tissue proliferation was found in the spleen (fibroadenia) and in the liver (cirrhosis).

The well-known Italian investigator assumes that the spleen is the original seat of the disease, poisonous substances developing in it and entering the blood, in this way causing anemia and hyperplasia of the connective tissue in the liver. In some cases Banti has had the spleen extirpated with happy results.

Senator[2] later made the same subject the object of his investigation. He also classes the cases of splenic pseudoleukemia in the group of Banti's disease. Etiologically, Senator believes that autointoxications play a large rôle, because in many of these cases the splenic enlargement was preceded by diarrhea.

Regarding the symptoms Senator lays stress upon the hemorrhagic diathesis, which often occurs here, as evidenced by hemorrhages of the stomach and bowel, these being frequently the first sign to arouse the attention of the patient. According to Senator the ascites is sometimes absorbed. The blood is characterized by oligocythemia, oligochromemia (possibly leukopenia).

Curschmann[3] and Maixner[4] then pointed out the

intimate connection between cirrhosis of the liver and profuse and sometimes fatal gastric and intestinal hemorrhages. In Curschmann's case the spleen was considerably enlarged, felt hard, was not sensitive to pressure, and projected beyond the border of the ribs by about four fingers' width. The liver was somewhat small, but plainly cirrhotic.

Curschmann explains the hemorrhages by the fact that in cirrhosis of the liver collateral communications between the portal system and the system of the vena cava occur (thus causing varices in the stomach, esophagus, and pharynx).

Maixner has observed seven cases in which hemorrhages from the intestinal tract were the first symptoms to appear during the course of the disease, and also frequently to recur. In all cases the hemorrhage was very severe; in some even the direct cause of death.

In all these cases the liver is considerably enlarged and reaches nearly a hand's width below the right margin of the ribs. The spleen is also considerably enlarged and of hard consistency. Ascites was present only a few times. At autopsy there were no ulcers found in the stomach, only dilated veins in the cardiac part and in the esophagus. Maixner explains these symptoms as follows: "Early and frequent hemorrhages from the intestinal tract, large splenic tumor, light and slow development of ascites, and continuous diarrhea can be easily explained by the presence of a collateral circulation, accompanied by venous stasis. Since this circulation is one of the most perfect, we can see why the fatal course of liver cirrhosis can be so long protracted."

The resemblance of these cases of Maixner with those of Banti is evident. The gastric and intestinal hemorrhages have been counted as one of the symptoms of Banti's disease by Senator long before Curschmann and Maixner.

Von Aldor[5] lately described four analogous cases of "hemorrhagic cirrhosis of the liver" and discussed the question, whether these cases are not identical with Banti's disease.

Under this heading also falls an important article by William Osler, who, two years before Senator, Curschmann, and Maixner, pointed out the occurrence of severe gastric and intestinal hemorrhages in splenomegalia. Osler[6] calls his paper "Splenic Anemia," and emphasizes the fact that in these cases there was no cirrhosis of the liver. In perusing the histories, however, we often find that the liver is enlarged and projects several fingers' width beyond the free border of the ribs. The blood shows moderate diminution of the erythrocytes, absolute diminution of hemoglobin, and frequently leukopenia. Osler's cases resemble clinically those of Maixner and Aldor to such a degree that they will have to be placed under the same category.

Preble[7] about the same time describes four cases of hemorrhage from the stomach and bowels in cirrhosis of the liver, and tabulates fifty-six other cases. In 80 per cent. of these cases esophageal varices were found. In his own four cases splenic tumor, cirrhosis of the liver, and ascites were present. The cirrhosis of the liver may also take the form of the hypertrophic variety.

After having given some of the principal publications on Banti's disease and some of its varieties, I would like to relate a few of my own cases.

Not including the cases of pure splenomegalia (the splenic form of Hodgkin's disease) I saw in the last twelve years eighteen cases, which belong clinically to the category of Banti's disease. I have tabulated them and placed them in three groups:

1. Pure form: splenomegalia, anemia, cirrhosis of liver, ascites.

2. Hemorrhagic form, showing, in addition to the symptoms just enumerated, gastric and intestinal hemorrhages.

3. Splenomegalia, enlargement of the liver, anemia, sometimes associated with grave gastric symptoms.

TABLE OF CASES OF BANTI'S DISEASE TREATED BY EINHORN DURING 1894–1906

GROUP I.

No.	Name.	Age.	Date.	Principal Symptoms.	Course.
1	Carl B	15	1897	Marked enlargement of spleen and liver, anemia, ascites.	Death by exhaustion.
2	Abraham S.....	45	1900	Anemia, splenic tumor, ascites, dyspnea.	Fatal.
3	John P	50	1902	Enlargement of spleen and liver, ascites and anemia.	Fatal
4	Jos. S.....	38	1903	Anemia, enlargement of spleen and liver, little ascites, achylia.	Unknown
5	John H C.	32	1905	Very large spleen, large liver, anemia.	Unknown.
6	Andreas K	30	1905	Very severe anemia, enlargement of spleen and liver, ascites; pain in bones, marked anorexia.	Fatal.
7	Jul C J	43	1906	Very large splenic tumor; liver markedly enlarged, ascites, dyspnea, later icterus.	Unfavorable, still under treatment.

GROUP II.

8	Nicholas W	40	1896	Great enlargement of spleen and liver, profuse gastric hemorrhages, recurring thrice in four months.	Fatal.
9	Caroline A.....	52	1906	Splenic tumor, liver considerably enlarged, severe anemia, frequent profuse intestinal hemorrhages, ascites.	Fatal.
10	Arthur, J M...	48	1905	Large splenic tumor, large indurated liver; gastric hemorrhages, ascites.	Fatal.

GROUP III.

11	William R.....	58	1894	Large liver, slightly enlarged spleen, anemia, hyperchlorhydria.	Cured.
12	Anton T. ..	33	1898	Liver and spleen enlarged, attacks of chills and fever without icterus.	Was improved for three years, then fatal.
13	Louis M. D.....	42	1903	Spleen and liver enlarged, severe anemia.	Cured.
14	Michael M. L .	48	1904	Spleen and liver enlarged, anemia and slight leucocytosis, dilatation of stomach with beginning pyloric stenosis.ischochymia, hyperchlorhydria.	Much improved.
15	Beni. L.....	34	1905	Spleen and liver enlarged, anemia	Unknown.
16	August F.....	32	1905	Liver and spleen enlarged, ascites, anemia, hyperchlorhydria.	Improved.
17	Elmer E.....	49	1902 and 1906	Liver and spleen are enlarged and hard, partially lobulated; ascites, dyspnea.	Improved 10 years.
18	Peter H K ...	50	1906	Liver and spleen enlarged, anorexia, occasionally vomiting.	Cured.

In most of my cases the liver was considerably enlarged and usually much firmer than normal; changes in the contour of the liver in the shape of round nodules were twice found. Regarding the ascites of the first group my opinion coincides with that of Banti, in so far as the ascites shows absolutely no tendency to absorption, and that it will return quickly when artificially removed. The hemorrhagic form is especially important, as it is often mistaken for ulcer of the stomach.

I would like here to sketch Case M. M., forty-eight years old, a politician, has always lived well, occasionally drank too much, when with friends, although not a habitul drinker; was attacked in October, 1905, while in the best of health by severe hemorrhage from the stomach. The amount of blood vomited was supposed to have been at least a quart, and an undetermined quantity was lost in the bowel. A week later he felt so well that, contrary to the advice of his physician, he attended a banquet with his friends. He ate everything, but drank very moderately. When he came home, toward midnight, he again vomited more than a quart of blood and became unconscious. The next day the hemorrhage returned.

I first saw the patient two days after the last hemorrhage. On examination a large splenic tumor was found; the liver was much enlarged and firm; a considerable amount of ascites was also present. The patient was then somewhat comatose. Three days later he died after another hemorrhage.

Another case, also belonging to the hemorrhagic variety, is the following one:

Mrs. Q., about fifty-two years old, has been suffering for about six months with diarrhea and repeated intestinal hemorrhages. She lost in weight and became visibly weaker. When I saw the patient I found the following conditions: A pale, well-nourished woman; chest organs normal; abdomen distended; splenic tumor of large size, reaching to a finger's width below the navel, with a smooth surface, and of firm consistency. The liver is considerably enlarged, projecting three to four fingers' width beyond the free margin of the ribs. Ascites can easily be detected; abdomen not sensitive to pressure; rectum and vagina show normal conditions; urine is highly concentrated and contains neither albumin nor sugar. The blood shows severe oligocythemia, also oligochromhemia, but no leucocytosis. The patient died a few days later from another profuse intestinal hemorrhage. An autopsy was not performed, but the case seems clinically to belong to this group; for in carcinoma of the intestines we meet with the enlargement of the liver, but not with the tumor of the spleen of such size.

The third group is especially noteworthy, because a cure may be effected. In this class of cases the enlargement of the liver exceeds that of the spleen, and frequently severe dyspeptic symptoms are found.

It will not be out of place to sketch a few of these cases a little more minutely.

Case I.—May, 1896. William A. R., fifty-eight years old, has never drank much and has never had any venereal disease or malaria. About a year ago the patient began to complain of lack of appetite, frequent eructations, constipation, and at times a feeling of oppression in the chest. The patient lost a little in weight and became much weaker. Soon dyspnea developed, particularly when walking, and occasionally also after dinner even without any exertion. Physical examination showed: Liver much enlarged and somewhat hard; contour regular; reaches down to the umbilicus. Spleen can also be palpated at least a hand's width below the left costal margin. It feels rather hard and has a smooth surface. The stomach contents show a high degree of hyperacidity; otherwise nothing abnormal. In the blood slight anemia without leucocytosis or plasmodia was found. The urine was free from albumin and sugar. Patient was treated with alkalies without, however, feeling much better. The condition remained about the same for nearly a year, except that the weakness increased. In May, 1897, the patient was compelled to remain abed, suffering from rise in temperature toward evening. He received 0.5 gm. of quinine twice daily, with 0.2 gm. of methylen blue once daily. Later he was treated with iodide of soda and iron. His condition improved slowly, and in November, 1897, patient could be considered cured. The enlargement of the liver and spleen had disappeared, and the strength of the patient had returned. Patient has been enjoying uninterrupted health ever since and is still alive.

Case II.—October 21, 1903. Louis M. D., forty-two years old, had always been well until about ten months ago, when he began to suffer from digestive disturbances. The appetite disappeared, and right after dinner usually a feeling of fullness developed. Severe pain was absent, vomiting occurred only rarely, whereas a marked degree of constipation was present. Patient lost steadily in weight, about forty pounds in all, and became exceedingly weak. He has never been drinking to excess and never had syphilis. On examination the liver is found to be considerably enlarged. The dullness commenced at about the fifth rib and reached to the umbilicus. The organ feels harder than normal and has a few superficial irregularities. Spleen also is much enlarged and projects about three fingers' widths beyond the costal margin. Its surface is smooth and its consistency harder than normal. The mucous membranes look pale and anemic. The stomach is not dilated and its contents show the presence of free HCl. in nearly normal quantity. The thoracic organs as well as the urine are normal. The diagnosis of hypertrophic cirrhosis of the liver is made. The patient received iodide of sodium and iron, was put upon a liberal diet, and his bowels were regulated. He improved from day to day, became stronger, and gained in weight. At the end of November, 1903, the boundary of the liver was found to be nearly normal; the spleen also was considerably smaller; it could only be palpated on very deep inspiration. He had gained forty-five pounds, and remained perfectly well.

Case III.—December 15, 1903. H. N. B., thirty-eight years old, was suffering for the last three years from frequent pains in the stomach, occurring usually from one to two hours after meals. These were relieved by the taking of food. Since the beginning of 1903 patient complained of fullness after meals and increasing weakness and lost forty pounds in weight. He has never been a heavy drinker, nor has he had syphilis or malaria. Patient is of a somewhat brown but not icteric complexion and looks emaciated and anemic. Examination reveals a marked enlargement of the liver. The dullness commences a finger's width below the right mammilla and reaches down to the navel. The liver is easily palpated, being somewhat harder than normal, but has a perfectly smooth surface. The spleen is only slightly enlarged; the dullness goes to a finger's breadth above the margin of the ribs. In the thorax there is nothing abnormal. Urine is free from sugar or albumin and contains no bile pigment. The blood shows a diminution of the erythrocytes without any marked leucocytosis. The stomach contents revealed marked hyperchlorhydria without any signs of ischochymia. The patient is given alkalies and iodide of sodium with iron. He is also liberally fed. Under this treatment the condition of the patient improved markedly, and two or three months later he was perfectly well. Spleen and liver are apparently perfectly normal, and there is complete euphoria. Two and a half years later I again saw patient. He told me that during that time he had remained perfectly well and had gained fifty pounds.

Case IV.—June, 1904. Michael L., forty-eight

years old, has been suffering for ten years from severe pains in the stomach, accompanied by frequent vomiting. Food seems to have alleviated the pain. For the last three years he has been using the stomach pump and frequently washes out his stomach in order to ease the pain. In spite of good care and apparently rational treatment, the patient kept losing flesh (twenty pounds) during the last year and became so weak that he had to spend the greater part of his time abed. Fever had evidently not been present, but intense paroxysms of pain in the upper abdominal region occurred, so that injections of morphine were required in order to afford relief. At present he is complaining of pains over the entire abdomen, of pyrosis, constipation, and great weakness. Status presens; thoracic organs are normal. Inspection of the abdomen reveals a protuberance of the upper part, especially toward the right, also peristaltic waves, running from left to right, occupying the region of the left side of the abdomen from the costal margin to the pubis. Clapotage is easily produced in this region. On palpation enlargement of liver and spleen is found. The first organ reaches to a finger's width above the navel, has a rather smooth surface, and feels harder than normal. The hepatic dullness begins a finger's width below the mammilla. The spleen can be felt as a smooth, oval tumor ten centimeters below the free edge of the ribs. It feels rather hard. The stomach is now emptied with the stomach tube and thoroughly irrigated. The contents show food remnants from the previous day, and also a high acidity (100), much HCl, and very many microorganisms (especially yeast cells). The diagnosis was made of a combination of Banti's disease with benign ischochymia caused by a beginning pyloric stenosis. Patient was then treated according to the usual methods for his stomach affection, and he improved from day to day. In September all signs of ischochymia and dilatation of the stomach had disappeared and hyperchlorhydria alone remained. He had also gained in weight in the meantime. The condition of the liver and spleen was the same. He was, therefore, advised to have his epigastrium treated two to three times weekly with *x*-rays. In January, 1905, the spleen could still be palpated, but it did not project beyond the free margin of the ribs. The liver had also become smaller, projecting two fingers below the ribs. He was given iron and atoxyl. I saw him for the last time in January, 1906. He attended to his business in 1905 and enjoyed good health. Since June, 1904, when I first saw him, he had gained fifty pounds and was free from subjective complaints.

In closely scrutinizing the cases of Group III, just sketched, the following may be said: We have to deal here with an affection in which the liver is considerably enlarged (often twice the normal size). Its surface is usually smooth, but not always. It sometimes has slight irregularities. Its consistency is usually somewhat harder than normal. The spleen is also enlarged; it does not, however, reach the size of that in Groups I and II. Severe stomach affections are frequently found (R, B, L) and seem to influence the course of the disease. A perfect cure frequently results.

It is difficult to classify these cases in any clinically well-defined group. We have to deal here with a hypertrophic process of the liver, which will also become normal under favorable conditions. The whole picture seems to resemble hypertrophic cirrhosis of the liver, if not identical with it. Fatty liver could hardly cause similar symptoms, especially the increase of consistency, which is usually not found in this affection. As we have to deal here besides with an enlargement of the spleen and anemia, I have placed these cases at present under the category of cirrhosis of the liver and splenomebalia, or Banti's disease.

Regarding treatment we must consider with which group and stage of the disease we have to deal. In Group I and II during the preascitic stage extirpation of the spleen might be considered, as first recommended by Banti. If operation is not decided upon, then *x*-ray treatment would be desirable. I have had good results with this treatment in one case of Banti's disease (Michael L.) and in two cases of pseudoleukemia splenica. The splenic tumor was reduced in these cases to such a degree that it could be felt only with difficulty underneath the ribs. This treatment was accompanied by improvement of the other symptoms.

Gastric hemorrhages will have to be treated according to the accepted rules; we may be slightly bolder in giving food in these cases.

In the ascitic stage of the first two groups the prospects of improvement are very bad. The fluid quickly reaccumulates after puncture, and thus the patients gradually approach their death.

It is altogether different in Group III. As mentioned above, we often meet with cures, not only in the beginning of the disease, but also when the symptoms have advanced.

It is essential to combat the stomach symptoms and to put the patient on a strengthening diet. I have also used sodium iodide in conjunction with iron, and sometimes arsenic, and usually obtained good results.

A BRIEF RESUME OF THE WORLD'S RECENT CANCER RESEARCH.*

By WILLIAM SEAMAN BAINBRIDGE, M.S., M.D.,

NEW YORK.

SURGEON, NEW YORK SKIN AND CANCER HOSPITAL; ADJUNCT PROFESSOR OF OPERATIVE GYNECOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON, NEW YORK CHILDREN'S HOSIPTALS AND SCHOOLS; CONSULTING SURGEON, NEW YORK HOME FOR DEPENDENT CRIPPLED CHILDREN; CONSULTING GYNECOLOGIST, ST. MARY'S HOSPITAL, JAMAICA, L. I., AND ST. ANDREW'S CONVALESCENT HOSPITAL, NEW YORK.

PROBABLY no disease has received more scientific investigation within recent years than cancer. Thousands of individual observers and a number of special commissions, both in Europe and America, have been devoting their entire time to the solution of some of the complicated problems concerning

* Read in part before the Practitioners' Society of the Oranges, Orange, N. J., April 27, 1906, and in full before the Atlantic City Academy of Medicine, Atlantic City, May 11, 1906.

cancer. The work has largely been one of negation. Certain general facts relative to the occurrence of cancer have come to be accepted by investigators both in Europe and America. Some of the theories concerning the etiology of cancer have been practically disproved, while others are still under consideration, the final verdict being *sub judice*. Many of the agents which seemingly gave promise of great usefulness have been proven inefficient, while others have been more nearly restricted to their legitimate field, which, in most cases, is a very limited one.

In a study of the recent literature concerning the various phases of this interesting subject one is fairly overwhelmed by the mass of material, statistical and otherwise. It would be impossible in a paper of this scope to do more than epitomize this world-wide research.

Occurrence.—Cancer occurs with the same essential characteristics throughout the vertebrate creation. It is found in all domestic animals, in wild animals, and even in fish, and in its development accommodates itself to the life-span of the individual animal. It occurs in animals with increasing frequency as age advances, whether the duration of life be long or short. In man malignant new growths are found in considerable numbers after 45 to 50 years; in the horse, dog, and cat after 9 years; in the trout after from 5 to 7 years; and in the mouse after 2 years. The maximum incidence, whether in man or animals, coincides with the decline of reproductive activity, and yet castration seems to have no influence in the time of occurrence of the disease. The fact that both carcinoma and sarcoma are found throughout the vertebrate creation, increasing in the same manner as life advances, suggests their similarity.

Cancer is comparatively rare in hot countries, especially in those whose inhabitants subsist largely on vegetable diet. With certain exceptions it seems to be prevalent where animal diet is mostly consumed. In this connection it may be stated with reference to the influence of diet on the development of cancer that there is a variety of conflicting testimony. From those who believe it traceable to the uric-acid diathesis, advocating a vegetable diet as a preventive, to Senn, who finds that the Eskimos, living on an almost exclusive raw meat diet, are absolutely immune from tumors of all kinds, there is a variety of opinions. In Borneo cancer is apparently unknown; in certain parts of China, Burmah, and India it is very rare, in Persia it is seldom seen, and in Africa it is much less common than in many parts of Europe. In Germany it is less frequent than in England or Sweden.

Black races are remarkably immune from cancer, yellow races are more prone to it, while the white races are the most liable.

It occurs when the tissues are undergoing retrograde metamorphosis, hence it is largely a disease of senility. Both carcinoma and sarcoma occur with increasing frequency as age advances.

It seems to be the consensus of opinion, among both European and American investigators, that cancer is undoubtedly on the increase, a fact not entirely accounted for by the present better diagnostic methods and the more accurate keeping of records. In the United States cancer is distinctly on the increase, census reports showing that from 1850 to 1890 the mortality from cancer increased from 9 to 33.5 to every 100,000 population. In England and Wales returns from the Registrar-General show the following annual ratio of deaths from cancer to each million of persons: In 1864, 385; in 1895, 755, and in 1900, 828. In France the mortality from cancer and other tumors has risen from an average of 840 per million (urban population only), 1887 and 1890, to 1,050 per million in 1898. In Germany, Switzerland, Austria, Norway, Sweden, Holland, Denmark, and various other European states, cancer has been shown to be increasing. In Ceylon it has increased markedly in the last decade.

The principal increase in cancer involves the alimentary tract. In 1900 there were 9,000 deaths from cancer of the stomach in the United States. According to Dowd, cancer of the stomach, as compared to other regions, comprises 31 per cent., and according to Mayo 30 per cent. of all cancers involve the stomach.

Certain observers are giving particular attention to the geographical distribution of cancer. They have found that in certain areas, notably in England and the United States, cancer is so prevalent, and the mortality rate so high, that such districts have come to be known popularly as "cancer belts." As a rule such areas are low-lying, damp, and generally watered by streams which periodically overflow their banks. High-lying, dry districts are relatively, though not entirely, immune. Lyon reports a cancer district in the towns of Plainfield and Edmeston, New York, comprising an area of 2.5 by 1.5 miles of rough, hilly farm country. An interesting illustration of a "cancer district" in a hilly, rough, well drained section is given by Lyon in the Monthly Bulletin of the New York State Board of Health. This area comprises seventy-five square miles in Brookfield township, Madison County, New York. Of the several villages in the township Brookfield furnishes the highest death-rate from cancer. Its population in 1900 was 485. Careful investigation among the inhabitants and the local physici ns revealed 84 deaths from cancer in the fifteen years from 1886 to 1900. Of the "cancer houses" in the village nine had a history of two or more cases.

Women are attacked by cancer much earlier and more frequently than men, and the disease develops in persons of either sex at an earlier age than formerly.

Etiology.—Various opinions exist concerning the causation of cancer, yet nothing definite has been established regarding the *essential* cause. The Harvard Commission discredits the parasitic theory, while the report of the Imperial Cancer Research Fund destroys all known theories of the origin of cancer, formulating, however, no new theory. Considerable work has been done at the Gratwick Pathological Laboratory by Gaylord and others which has attracted more or less attention from both the medical and the public press, but so far nothing of practical value has been established. It has been shown that mice can be infected by cancer from like species, cancer developing in a certain proportion of cases. On the other hand, some of the mice have seemed to spontaneously recover, at least for the time being. Much of the recent experimental work points to the *cell* as the essential element in the development of cancer, some investigators holding that external agencies probably play little or no part in determining the incidence of the disease.

Bashford, of the Imperial Cancer Research Fund, says, "Our observations on animals show that malignant growths are always local in origin, and of themselves produce no evident constitutional disturbance whatever. These facts are in full accord with accumulated experience in man." The systemic conditions which result from cancer are due to the breaking down of the tissues and the formation of toxins, which ultimately gives the characteristic cachexia.

In addition to race, climate, topography, age, and sex, mentioned heretofore, the following factors seem to be more or less involved as predisposing causes of cancer:

Heredity.—According to von Bergmann, heredity plays a relatively unimportant part, though there is no doubt that certain families are predisposed to cancer. Others, after careful study, state that heredity is of no importance in the development of cancer. Mr. Roger Williams, after a careful analysis of the family histories of more than 700 cases of benign and malignant tumors, concludes that a history of heredity indicates little more than a predisposition. Mr. Butlin believes heredity influences cancer, but finds, from the cases examined, that there were scarcely any cases in which the history of cancer was divided between the families of both sides.

Cicatrices.—Scar tissue, when subjected to continuous irritation or marked injury, is, in many cases, prone to undergo a malignant change. This is found to be true in the female breast, where the glandular tissue has been largely supplanted by connective tissue of suppurative mastitis; also in the cervix uteri, where scar tissue results from cervical tears. Craig failed upon investigation to find a single case of carcinoma occurring in a successfully repaired cervix, except where trauma had subsequently occurred, and A. Lapthorn Smith says that uterine cancer has almost disappeared from his clinic and from the practice of his friends for the simple reason that women are not allowed to go round with a cervix full of scar tissue.

Benign epithelial growths.—Warts, moles, and other growths on the surface of the body when undergoing irritation not uncommonly break down and take on malignant characteristics. Very little irritation is sometimes necessary to transform a papilloma into a beginning epithelioma.

Chronic inflammatory conditions, by lowering the vitality of the tissues involved, render such areas more liable to malignant change.

Traumatism.—According to von Bergmann, a single contusion of the breast may be the predisposing cause in the development of cancer, especially when the trauma occurs at a time when the woman is liable to carcinoma. The influence of trauma is emphasized especially in the cases of neoplasms that develop in regions having no special predisposition to the formation of tumors.

Zeigler found that of 170 cancers of the breast there was a history of trauma in 37 cases, or 22 per cent. Snow found a history of trauma in 11.5 per cent. of 9,600 cases of carcinoma of the breast. As in cases of maternal impressions, these and similar statistics are likely to be misleading. In the case of a child which is "marked" a direct leading question will almost invariably call forth statements concerning some supposedly causative occurrence; so, in cancer, if it is suggested to the patient the history of injury may be easily obtained. We must carefully weigh all phases of the case in a purely judicial manner when tracing the causal factors. Law suits involving traumatism as the cause of cancer are becoming more and more frequent, and it is of the utmost importance that we keep concise and clear histories in such cases, not being influenced entirely by the patient's estimate of the matter. An injury may result in the development of cancer, but as a rule it produces evident changes in the area affected at the time of the receipt of the traumatism and some evidence of these changes remains until the appearance of the cancer. In this connection I quote the testimony of the late Dr. George R. Fowler in the case of Martin *versus* the Brooklyn Heights Railroad Company, May, 1905: "My conclusion from my personal experience, and that is supported by the experience of and writings and teachings of the best men in the profession, is that traumatism does not bear the relation to the production of cancer of the breast that it was formerly supposed to."

A careful study of statistics, according to Williams, disproves the opinion that traumata are efficient causes of cancer. This, in the judgment of the writer, is a field for further careful study.

Senn believes that all tumors originate from an original matrix of embryonic cells of congenital or post-natal origin, and that in the absence of such an essential histological basis no exciting cause or combination of exciting causes will result in the production of cancer.

Chronic Irritation.—It is undoubtedly true that repeated or chronic irritation, as from the edge of a corset pressing upon the breast, or the irritation of eye-glasses over the nose, many times causes malignant disease.

Malnutrition.—It is generally conceded that lowered vitality, other things being equal, seems conducive to the development of cancer. Mental depression also plays some part, according to some investigators, being particularly noticeable as a causative factor in women.

Treatment.—In the matter of treatment recent investigations have been largely a work of elimination. The field of usefulness of the various non-operative methods has been markedly narrowed, there being practically nothing left but operative procedure, except for a limited number of primary and secondary growths which may be cured by other means.

The field of the *x*-ray in the treatment of cancer, so popular a short time ago, has gradually narrowed during the last year. The consensus of opinion now is that it has absolutely no curative value in deep-seated cancer. It *may* cure localized superficial cancer, and again it has produced it, and may hasten metastasis. Its field in the treatment of malignant growths would seem to be in superficial secondary recurrences, where it has undoubtedly been of great service in many instances; also in lessening suffering in some inoperable cases.

Serum treatment has been fraught with disappointments. Doyen's serum has proved to be absolutely of no real value in the treatment of malignant disease. The Committee of the French Academy of Medicine, specially appointed to investigate this serum, reports that in not a single case treated with it was there any evidence of cure or even of amelioration. This report is confirmed by a special committee sent from London to Paris to make a careful study of this method of treatment. This would seem to put an end to the claims for Doyen's serum.

Radium is frequently referred to in the literature, but in the hands of the Committee of the French Academy of Medicine it has fared little better than Doyen's serum. Abbe is the only prominent reviewer of the subject of cancer who appears to think well of it. Schücking reports some favorable results with radium, confessing, however, that radium rays cannot yet be said to possess a curative action in so-called inoperable cases of cancer.

Adrenalin in large doses, according to the report of the Imperial Cancer Research Fund, by setting up inflammatory reaction in the supporting structure of the tumor, causing bleeding into the tumor, may carry off enough of the necrotic material and cancer

cells to produce a retrograde change in the tumor and an apparent cure. Radium is said to act in the same manner.

Coley's method of injecting the mixed toxins of the bacillus of erysipelas and the bacillus prodigiosus seems, from a careful search of the literature, to have been practically abandoned except by Coley himself. In some rare forms of sarcoma it is reported by a number of observers to have caused retrograde changes, but no law of control has been established. In a recent article Coley again urges the claims of his fluid as a remedial agent and reports some remarkable cases.

Oöphorectomy has caused the retrogression and disappearance of a number of mammary tumors, always, however, ultimately followed by death from the disease.

Caustics and pastes may cure some cases of superficial growths, but with pain and with longer time, as a rule, than is necessary with the operative treatment.

Surgical treatment has, largely by process of elimination, been established on a firmer basis than ever before. It is the sheet-anchor in our work to-day, and, as a rule, the only bridge across which safety lies. This may be epitomized under the following heads:

(1) Removal of inflammatory conditions, cicatrices and benign tumors before they have undergone any malignancy, thus paradoxically curing the cancer before it exists.

(2) Removal of cancer when present, with a margin of healthy tissue, and the extirpation of lymphatic vessels and lymphatic nodes in close relation to the disease.

(3) Free exicision, even running risks, if necessary, in order to accomplish complete eradication of the disease.

(4) In so-called "inoperable" cases, where the disease cannot be entirely eradicated, removal of as much as possible, shutting off the blood supply to that which cannot be removed, so that the growth may be slower, is certainly a rational procedure. In inoperable cases of cancer of the uterus good results have been reported from Chrobak's clinic by cauterizing with fuming nitric acid or with Paquelin cautery, after removal with a sharp spoon of as much as possible of the diseased tissue.

(5) In those cases which are truly inoperable, where the entire cancer cannot be removed, or even a portion of it, in many cases great comfort may be afforded by cutting nerves and relieving secondary conditions which cause so much suffering.

HABITUAL CONSTIPATION, VIEWED FROM THE STANDPOINT OF MODERN EVOLUTION OF DIETETICS, IS A PHYSIOLOGICAL PHENOMENON.*

By C. D. SPIVAK, M.D.

DENVER, COL.

The conception of regular and irregular movements of the bowels is vague and indefinite as far as the physician is concerned. A movement of the bowels once a week, or even at longer intervals, has been called regular by many of our patients, and one or two movements daily are often designated as constipation, if these movements leave the patient in an unsatisfied and ever-longing state of mind. We have no clinical methods by means of which the physician could make a diagnosis of constipation, and every intestine, therefore, is a law unto itself. The physician, when assuming the responsibility of treating a case of constipation, is guided by the statement of his patient; he accepts the definition of the word as applied by the sufferer to his particular case. Indeed, the physician has no choice in the matter and must accept the statement of the patient; there is not another disease in the whole range of medicine where malingering could be practised with as little danger of detection. One who practises rational medicine will endeavor to find out the etiological factors which may give rise to this condition, and, if found, treat the constipation by removing the cause. If, however, after a thorough examination of the patient, no pathological condition is found which would justify the existence of constipation as a symptom, we simply prefix the term "constipation" by the word "habitual," and thereby raise it to the dignity of a disease *sui generis*. Having cleared our conscience from the responsibility of looking for a cause, we start out with our energetic treatment. We change the mixed diet to one containing a large percentage of residue of indigestible substances; we increase the quantity and frequency of meals; we use ether spray over the abdomen; we stretch the sphincter, we insufflate, inflate, dilate, and plug the rectum; in short, we exercise our ingenuity to irritate the bowel, dietetically, thermically, mechanically, electrically, etc., so as to increase its peristaltic movements, and induce premature delivery of the fecal matter. Here, too, we encounter another difficulty. Since the number of evacuations within any given time does not constitute a criterion of normal or abnormal, the question which each physician has to solve is, How often must the bowels move to justify the statement that the patient is cured? All physicians endeavor to secure one movement every day, and anything less than that is not considered a successful cure. Why should one movement a day be considered normal? Why not two movements in one day, or one movement in two days? By what are we to be guided? As in the case of diagnosis, the physician must be guided by the patient; so it is with the treatment. The physician is at the mercy of the patient. He it is who is to decide when he is cured or not; and upon his word depends the success or failure of the treatment. Is it not possible that the many failures to cure constipation which every physician has to his discredit, are due to the fact that these patients would do well with a movement of the bowels once in two or three days?

Eminent clinicians and investigators like Leichtenstern, Ewald, Dunin, Meinert, Glenard, and others have each brought forward an ingenious theory as to the causation of habitual constipation, all of which remain mere conjectures. Nothnagel makes the broad statement that habitual constipation is "a primary and independent form of disease, and must be considered as such." But this problem will not be solved until we have learned more about feces. It is a sign of the times that within the last two years have appeared two editions of Schmidt's and Strassburger's work on feces and more than a dozen theses and monographs on the subject.

At a recent meeting of the Naturforscher Gesellschaft Ad. Schmidt declared that all the theories as to the causation of constipation hitherto proposed are untenable, and that the only rational explanation of this obscure condition is to be found in the theory of intensive utilization (*intensive ausnutzung*) by the bowel of the nutritive ingredients contained in

*Read at the ninth annual meeting of the American Gastroenterological Association, held at Boston, June 4 and 5, 1906

the food, which explains the small quantity and dry quality of the fecal matter found in the majority of cases of true habitual constipation.

Now, the question arises, is intensive utilization a pathological or physiological phenomenon? For some time I have been conducting a series of observations on patients suffering from habitual constipation, with a view of ascertaining the quantity of food ingested and the corresponding quantity of fecal matter expelled.

The factors that enter into these studies are so many and varied that it will require many more observations to be recorded and a very careful sifting of the facts and figures, before they can be tabulated and made available. The greatest difficulty which one meets from the outset is the absence of a standard as to either quantity or quality of fecal matter in the healthy individual, so that there is nothing to compare with or be guided by. Then, each ingredient of food produces a certain quantity and quality of fecal matter. This is an important study which has been attempted only lately by Lynch, and which will yield valuable results in the future. Lastly, each healthy man possesses a certain capacity for the amount of food ingested and absorbed, as well as for fecal matter produced, the relation between the two not being a constant number. Many persons eat large meals and produce scant movements of the bowels, and vice versa.

The observation on the rectopath is made more difficult because he or she whose mind and soul dwell in the nether regions does not "take much stock" in the scientific side of the question, and therefore, with the exception of a few intelligent persons, does not permit one to observe the course of constipation under normal conditions. They insist on immediate change of diet, the use of laxatives, enemas, all of which create an abnormally abnormal condition.

But, notwithstanding the fact that I am not ready to present a finished report of my labors, I have already gathered enough data to form in my mind a composite picture of the sufferers from habitual constipation and to assert that in patients thus afflicted, especially males who work hard, enjoy a good appetite, sleep well, and who keep up their bodily weight, the constipation is due to physiological causes, *i.e.* the food they ingest is thoroughly utilized, little residue is left, and it is natural for such patients to have a movement of the bowels at intervals of two, three, or more days. Such a condition cannot be regarded as pathological. To prescribe drugs, a laxative diet, or the various other irritants means eventually to induce a catarrhal condition of the bowels.

The question naturally arises, if the small quantity of fecal matter and the long intervals between the movements is a physiological condition, it should not give rise to any inconvenience or discomfort and we would not expect such a normal man to seek the services of a physician.

I will explain this by a hypothetical case: A man who is accustomed to have a movement of the bowels, say once a day immediately after breakfast, is called away immediately after breakfast, or must go without breakfast. What happens? The nervous mechanism of the intestine was wound up by the clock-work habit for twenty-four hours. Something interfered. The bowel is irritable for an hour or longer, the man feel uncomfortable, and gradually the irritation subsides, and the discomfort it occasions disappears. If the subject does not pay any attention to it—if he does not consider himself in duty bound to have a movement of the bowel once a day and every day of his life, he will go to sleep and wait for the next morning until after breakfast, when a regular movement, probably larger in quantity will be the result. If, however, instead of letting nature take care of itself, the man will come home in the evening and begin to make efforts and strain to have a bowel movement, or will take a laxative, insert a suppository, etc., he will at once create an abnormal condition. If he induces artificially a movement of the bowels, say late at night, he will in all probability miss his regular movement the following morning, notwithstanding the extra straining he may do. Again he may induce a movement in the evening and thus start up constipation. In this case the little discomfort which the patient experienced at the beginning and which every healthy body is and should be able to throw off without leaving any trace behind, has started on its way a case of habitual constipation; the patient interpreted the temporary discomfort he experienced as the outset of a grave malady, "constipation," to ward against which he immediately instituted energetic prophylactic measures.

This goes to illustrate that we can cultivate two kinds of habits, and especially in relation to movements of the bowels. One habit is that the bowels should move at regular intervals, and the other is the habit of breaking that habit whenever necessary. As Sir James Paget (Studies of Old Case Books) said: "These half involuntary organs (rectum and bladder) are good servants but very bad masters; the more they are indulged the more peremptory they become; . . . they should be educated to subserviency; . . . any one with a resolute will may easily teach them."

This sort of constipation is simply due to a loss of faith in one's self and in the elasticity and pliancy in the functions of the body, to a fear that a slight disturbance from the usual habits may lead to profound pathological changes. It is a fear of constipation—a phobia.

There are others who think they suffer from constipation simply because they have made up their minds that they will not be cured unless they have one movement daily.

Humanity is undergoing profound changes in regard to dietetics. We may consider the last century as a transition period. At no time in the past have the civilized nations consumed so much meat, eggs, milk, and especially sugar as during the last century, and the use of the latter article is growing from year to year. The number of predigested, prepared, dextrinized foods is increasing daily. The high efficiency of the dental art and the greater stress laid upon the proper mastication of food all these factors produce certain changes in the human organism, which manifest themselves by a reduced quantity of the fecal matter and less frequent need for emptying the bowels.

From the above consideration, I wish to make the following deductions:

Habitual constipation in a good many cases is due to a mistaken diagnosis. The patient makes the diagnosis himself based upon his sensation only. Once the diagnosis of constipation is made, and then corroborated by the physician, the diagnosis becomes an etiological factor.

The tendency of civilized life in general and of modern dietetics in particular is toward the production of lesser quantities of fecal matter and less frequent intervals of evacuation.

There is no doubt that the habit of regularity is beneficent, but no matter what one's philosophy is regarding free will, it is right that men should resolve that they will not allow every unusual sensation to become a source of morbid concentration.

The treatment of habitual constipation should be directed more toward rectifying the errors of the mind than those of the body; the fear engendered in the patient of an impending calamity should be allayed by impressing upon him the simple, physiological truth that certain foods are better absorbed than others, that it is not imperative for the preservation of good health to have a movement of the bowels daily, nor is the small quantity indicative of disease.

ACROPARESTHESIA: A STUDY OF TWO HUNDRED CASES.

By W. W. LESEM, M.A., M.D.,

NEW YORK.

Acroparesthesia may be defined as an affection of the peripheral nerves characterized by burning, pricking, pins-and-needles, numb, crawling, itching, or breaking sensations distributed usually over the extremities involving not infrequently, however, the head, the face, the chest, the back, or the abdomen, rarely the viscera. Among 200 cases seen at the clinic during the past seven years, 189 or 94½ per cent., occurred in women. Acroparesthesia is a disease of adult life, the majority of the cases occurring between the ages of thirty and forty. Of our series of cases, less than 16 per cent. developed before thirty, while in only two instances had the affection appeared before twenty; in 12 per cent. the patients developed the disease after fifty. Heredity does not seem to play an important etiological rôle, although frequently the disease has occurred in more than one member of the same family. The preponderance of Jewish patients in the dispensary renders it impossible to determine whether, as in diabetes, the Hebrew race is particularly prone to this affection or not.

Syphilis, rheumatism, the excessive use of alcohol, tea, or coffee, do not appear to act as important etiological factors in producing the disease. In nearly 20 per cent. of the cases occurring in women the disease was associated with puerperal, menstrual, or climateric disorders; the condition of these patients under appropriate local treatment was rapidly ameliorated.

Acroparesthesia is an affection formerly thought to be dependent largely upon constant exposure of the patient's hands to water. Inasmuch as practically none of our patients has been engaged to any great extent in washing, we may readily dismiss this erroneous idea from our consideration, even though the condition of some of our patients apparently was aggravated by exposure to damp weather. Acroporesthesia has been practically disregarded in neurological literature save by a few investigators, among whom are Bernhard, Dana, and Collins. Inasmuch as over 200 cases have occurred at Dr. Collins' Neurological Clinic at the Post-Graduate Hospital during the past five or six years, in other words, inasmuch as nearly 3 per cent. of all our patients under observation have manifested this disease, a more careful consideration of the etiology of this affection may not be inappropriate.

In 33 per cent. of our cases a history of obstinate constipation of long duration was obtained, while of the remaining 67 per cent., 20 per cent. complained of chronic dyspepsia. In 53 per cent., therefore, we have found some chronic disturbance of the gastrointestinal tract. Examination of the urine of forty patients suffering from this disease elicited the fact that in about 50 per cent. of the urines examined a positive reaction for indican was obtained. Finally, it has been Dr. Cox's and my own experience that the vast majority of all the patients suffering from acroparesthesia have been grossly obese and of sallow complexion, as if suffering from some autointoxication. Faulty metabolism, faulty elimination, and autointoxication, therefore, may be considered as the most important exciting causes of acroparesthesia.

There is, however, another important disorder at the basis of this disease, viz., disturbances of the circulatory system. Vasomotor paresis, arteriosclerosis, or excessive alkalinity of the blood was present in more than 33 per cent. of all our cases. These disorders were manifested symptomatically by hot and cold flashes, profuse perspiration, and coldness of the extremities. In cases of arteriosclerosis seen at Dr. Collins' clinic in many instances acroparesthesia was the only symptom for which the patient presented himself for treatment. Examination of the blood of a series of twenty patients suffering from acroparesthesia elicited a range of alkalinity of from 1.8 to 2.6 per cent., the average being 2.4 per cent. In the hemalkalinometer test 2 per cent. is considered normal.

From the above we see that circulatory and gastrointestinal disturbances appear to account for the vast majority of our cases; menstrual and puerperal disorders occurred in 12 per cent., while occupations such as tailoring and constant immersion of the hands in water occurred as an etiological factor in 1 per cent. In 9 per cent. of all the cases no ascertainable cause could be elicited.

The symptoms vary with the intensity of the disease. Some patients complain merely of transient pins-and-needles sensations in the fingers, the hands, the arms, the toes, the feet, or the legs, or in all of these. In others the disease is characterized by burning and pricking sensations in the extremities and in the back. In 33 per cent. of all cases tingling and numbness predominated. In 8 per cent. the chest was the seat of the disease, while in 4 per cent. the affection manifested itself primarily in the head or the face, involving later the extremities and the trunk. These last-named cases are usually the most aggravated. In the more severe forms of acroparesthesia the pain is so intense as to render the patient's life miserable; sleep is impossible, walking painful, and the use of the hands attended with excruciating agony. By far the most severe form is the visceral type. Here the disease manifests itself with dull cramping pains over the precordium, the stomach, or the intestines, involving later the extremities and the trunk. In the severer types of acroparesthesia hot and cold flashes, dull or boring frontal headache, choking sensations, nausea, gaseous eructations, palpitation of the heart, coldness of the extremities, and mental depression frequently manifest themselves.

In the mild forms of acroparesthesia no physical signs are present. In the more severe forms we meet with areas of tenderness over the vertebral borders of the scapulæ, tenderness beneath the clavicles and over the superficial nerves of the extremities. The deep nerves are not involved. Diminution of the tactile sense of the hands, of the fingers, and of the feet is of frequent occurrence. In but few instances is there any noticeable tremor present. When the head or the face is involved, the tenderness of these parts usually is most exquisite. Only in the severer types are the deep reflexes exaggerated.

Vasomotor paresis accompanies the majority of all well-developed cases. The blood-pressure as determined by the Riva-Rocci apparatus is not increased save in those cases which have arteriosclе-

rosis as their etiological basis. Seven per cent. of all cases seen presented a more or less marked degree of anemia.

The disease runs either a short course or becomes chronic and progressively worse. The types most amenable to treatment are those dependent upon puerperal and climacteric disorders, and upon auto-intoxication. The majority of cases seen by us have lasted for many years, beginning with mild pins-and-needles and pricking sensations, gradually increasing in severity and rendering the life of the patient miserable. Not infrequently neuralgia and multiple neuritis develop in the severer forms. The routine treatment of acroparesthesia in the clinic consists in the administration of 10-grain doses of calomel every fifth night, followed by a purge in the morning, or the daily use of cascara as a substitute. Three times a week the patient receives an application of the static spray. The medication in vogue consists of the so-called black mixture:

℞. Sodi. brom..... ℥ss.
Pepsin ..... gr. xv.
Carb. ligni..... ℥iss.
Olei menthæ viridis..... gr. iii
Glycerin ..... ℥iii
Aquæ .....ad. ℥ii
Sig. Teaspoonful three times a day.

In but few instances has this method of procedure either ameliorated the suffering or shortened the duration of the disease. By far the most satisfactory results have been obtained by the use of increasing doses of strychnine combined with 15-grain doses of sodium bromide three times a day.

Case I.—Mild type of acroparesthesia. J. W., woman, married, aged 40. Family history negative. Personal history throws no light upon her present ailment. She has had no children or miscarriages. She says she was always well until a few months ago, when she experienced peculiar sensations in the arms and the legs. At times these sensations were pricking in character, at times needle-like. She has never suffered from headache, palpitation of the heart, or gaseous eructations. Since the onset of her present trouble she has never suffered any severe or acute pain. Her menopause occurred one year ago. This is a case of acroparesthesia with the menopause as an etiological basis.

Case II.—Mild type. D. R., woman, single, aged 20, cigarette maker. Family history negative. Patient was always well until four years ago, when she experienced needle-like sensations in both legs; these pains did not extend beyond the knees. She does not suffer from headache, palpitation, pain in the back or in the arms. Menstruation regular. Sleeps well. No pulse fullness. There is increased tenderness over the peripheral nerves of the legs. Otherwise the physical examination is negative. Examination of the urine showed a decided reaction for indican. This patient has been for two years under observation and has grown progressively worse.

Case III.—L. I., woman, married, aged 36. The patient says she has always had more or less abdominal paresthesia, accompanied by cramps in the stomach. At the present time she comes complaining of pulling, drawing pain in the right arm and the foot. This pain is frequently burning in character, at times crawling in nature, and when crawling is most severe. The pain is more or less constant. The arms and hands are also involved. At times these pains shift from one part of the body to another and then the pain is less intense, but whenever it becomes localized it is most excruciating. Frequently she experiences sticking and burning sensations in the fingers. On examination there is marked tenderness over the vertebral borders of the scapulæ; some tenderness beneath the clavicles, and some slight tenderness over the nerve trunks of the legs. Examination of the urine showed it to contain indican.

Case IV.—J. R., woman, married, aged 36. Patient was always well until one month ago, when the present trouble began. She has had six children; no miscarriages. For the past month she has had drawing pains in the chest, the legs, and the arms. She also suffers from severe headaches radiating to the top of the head which, together with the sensations previously enumerated, prevent her from sleeping.

Case V.—H. B., woman, married, aged 54. She had rheumatism 12 and 4 years ago. Three years ago she experienced pins-and-needles sensations involving the top of head, the shoulders, the arms, the back, and the legs. The pains were most severe in the feet, the back of the legs, and the hands and fingers. Usually the pains begin in the afternoon, reaching the height of their intensity at night, and disappear in the morning. The condition is aggravated by damp weather. Owing to the intensity of her suffering she is unable to sleep at night. Bowels regular. Appetite poor. Urine contains indican.

Case VI.—H. A., single, woman, aged 34. Two years ago the patient experienced itching, crawling, pricking, and tingling sensations in different parts of her body. These gradually became worse, and during the past year general symptoms manifested themselves, viz., intense excitement with quick, shallow breathing, tense muscles, aching of every nerve when engaged in conversation or writing. Her nerves appear to quiver and the diaphragm feels like a tense drum. She has crying spells and slight attacks of temper which she is unable to control or check. Flushings of the face and roaring or ringing in the ears are frequently present. Her hands and feet are cold and clammy. At times she experiences a general tired-out feeling, her will-power and ambition alone enabling her to pursue her work. At times she experiences blurring of the visual fields and great difficulty in concentrating her mind for any length of time upon any one subject. She has palpitation of the heart, especially at night, and poor circulation characterized by coldness of the extremities and chills. Frequently in the morning the patient experiences a heavy, dragging feeling about the heart, accompanied by a sensation of pressure. During her menstrual period she likewise experiences sharp pains over the heart. The gastric symptoms are acidity, gaseous eructations, bloating, gnawing sensations over the epigastrium, and loss of appetite.

290 West One Hundred and Thirty-Seventh Street

REPORT OF TWO CASES OF VARICOSE VEINS SUCCESSFULLY TREATED WITH THE X-RAY.

By JAMES C. McGUIRE, M.D.,
WASHINGTON, D. C.
PROFESSOR OF DERMATOLOGY, GEORGETOWN MEDICAL COLLEGE

Though I have had free access to the books, pamphlets, and card index of the Army Medical Museum, my own rather extensive library, and other sources, I have been unable to find any reference to the treatment of varicose veins by means of the Röntgen rays, and, so far as I am aware, the use of this therapeutical measure for the relief of the trouble is entirely unique. I was induced to take up the treatment by noticing the un-

*Read before the Medical Society of the District of Columbia, June 6, 1906

expected results in a case of eczema and varicose ulcer on the leg, and from reading a number of cases of "*Wine Mark*" that had been successfully treated by irradiation.

The results I have obtained have been most successful, and therefore I consider them well worth reporting.

Case I.—Mrs. E., forty-five years of age, eczema of both legs, complicated with varicose veins and an ulceration the size of a silver dollar on the right leg. After several months' treatment with local applications, bandages, etc., the eczema was cured; the ulcer, treated by application of pure carbolic acid and iodoform dressing, was reduced about one half in size, but even after weeks of the most vigorous treatment of the ulcer, it could not be further healed over or contracted. I began treatment with the *x*-ray March 30, 1906; medium tube; distance, eight inches; time, five minutes; every other day till April 12 (six irradiations), when the patient complained of a severe burning sensation. There was much inflammation of the skin extending over the whole surface of the leg, and the ulcer was angry looking. I stopped the applications for four days, when, the inflammation subsiding, I again applied the rays. The next day the part was found still more inflamed, and crusted over; but during the course of the following five days without *x*-ray treatment the dermatitis gradually subsided, and had entirely disappeared by the end of the week. The excessive desquamation of the skin had then disappeared and the ulcer had ceased to discharge, looking glazed and healthy and reduced to the size of a ten-cent piece. During all this time, much to my surprise, the varicose veins were growing smaller and smaller, till on May 20 they had entirely disappeared. The ulcer was completely healed over and covered with smooth, scar tissue, and there was no sign of the eczema. I neglected to say the bunch of knotted veins, to which I have referred, was situated just below and partially around the ulcer, and there were a few small enlarged veins elsewhere scattered over the surface of the leg.

Case II.—Mr. R., fifty years of age, referred to me by Dr. Lloyd Magruder, treated and relieved of a severe papular eczema of the arms and legs. On the calf of the right leg was a large accumulation of varicose veins, about the size of half an orange, two or three inches in diameter, extending an inch or so above the surface. I began the treatment with the *x*-ray on March 31, 1906, with a medium tube, one inch spark; distance twelve inches; time, ten minutes; irradiation continued twice a week till May 7 (ten applications), when the tumor was noticed to be considerably reduced in size. Since the above date the treatment has been carried out every other day, very gradually reducing the time and distanec of the tube. At this date, June 4, the same tube being used, distance five inches, time of exposure fifteen minutes, though there has been only a slight reaction of the tissues, the mass of knotted veins—in fact the whole tumor—is reduced fully one half in size, and even the bluish discoloration of the cuticle is fading away. This result is particularly remarkable from the fact that it was obtained without producing any great reaction of the tissues. Theoretically considered, this would seem to be impossible, yet we here appear to have a practical demonstration, however we may explain it.

I am sorry not to be able to present the two cases to the society, but Mr. R. declares he will be glad to bear me out in regard to the truth of the statements as above reported. It would seem difficult, if not impossible, to explain such results of treatment by means of the Röntgen rays, yet it is no more so than our attempts to demonstrate the favorable results obtained in treating certain diseases by the administration of drugs.

The day of epiricisin in the use of this remedy has passed, and, as Dr. Pusey has said, "it's use is much less empirical than the use of quinine, mercury, and arsenic. The first case reported, in which there was such a severe reaction of the tissues, might be explained on the same theory as the explanation given for the favorable results obtained in cases of nævus vascularis reported by different writers, particularly in the case of Dr. Jutassy, in which there was a 'wine mark' extending over half the face and the mucous membrane of the mouth and nose. In this case, after setting up violent reaction, when the epidermis was renewed, it was of normal color, and eighteen months afterwards there had been no relapse." The author attributes this result "to the action on the blood-vessels, which were successively contracted, inflamed, and obliterated."

It would seem to be more difficult to explain the favorable results obtained in the second case—that of Mr. R.—for, as I have said, there was only a slight dermatitis produced. There is no question but that the rays cause contraction and atrophy of the tissue, that congestion is diminished, and that tissues of low vitality easily break down; the contraction of the muscular coats of the vessels causes a diminished blood supply, and, according to Snow, "the vibratory influence of the rays restores tone to the muscular coats of the arterioles, and at the same time induces a more active local metabolism." The favorable results obtained in such cases might also be partially explained by the fact that the ray has some inherent property of its own, that is peculiar to itself, independent of either light or electricity, on the hypothesis that all normal tissue has its ultimate particles, its corpuscles or electrons in proper relationship to each other, and that any change in this arrangement will bring about abnormality, or, in other words, a pathological state, and that the rays have the power of restoring these particles to their normal condition and relationship to each other. This explanation may at first seem far fetched, but as we become more familiar with the theories that have been advanced from time to time, to explain the ultimate division of all matter, we cease to wonder at any new hypothesis that may be suggested. When we consider the behavior and the relationship of the corpuscles or ions to each other, particles too minute to measure, yet so numerous that hundreds of thousands of them are contained in a mere atom, traveling at the rate of a million miles a minute, our only wonder is that the severe shocks, trials, and tribulations, to which these cells are subjected, should only cause disease, we marvel why the frail body itself is not soon completely disintegrated.

Postoperative Retention of Urine is treated as follows by Anspach: If retention of urine is present after operation, catheterization of [illegible] is performed and the catheter inserted into the distended bladder, and as soon as the urine begins to flow the catheter [illegible] c.c. of a 25 per cent solution of boroglyceride is injected into the bladder. The catheter is then withdrawn. Urine is usually voided [illegible] after the procedure, and in very many cases no further difficulty is experienced.—*University of Pennsylvania Medical Bulletin.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, September 1, 1906.

THE MORTALITY OF GALL-BLADDER OPERATIONS.

IT is often remarked that statistics are unreliable and can be employed to prove either side of a contention, and yet it may also be said that the interest in statistical studies is quite general, and particularly if they are compiled by some well-known man, they cannot fail to excite interest. We venture to say that a review, for example, of fifteen hundred operations on the gall-bladder and bile passages, done by two men within a limited period of years, will meet with the compliment of extensive quotation. In the space of fifteen years, the brothers Mayo (*Annals of Surgery*, August, 1906) have themselves performed the number of operations referred to, and as the work has been done under nearly identical conditions, their results must necessarily be of value in certain directions.

Mortality, permanence of cure, and disability arising from the operation itself are the three most important considerations in the surgical treatment of any disease, and the Mayos' investigations have been conducted with the view of elucidating the truth in regard to these essentials. The operative mortality, to begin with, was 4.43 per cent., including deaths from all causes. Cholecystostomies numbered 845, with a mortality of 2.13 per cent., and the writers consider that from the standpoint of mortality, this is the safest operation for the average case. The objection that gallstones may reform in the gall-bladder does not seem to worry these operators very much, as they claim to have seen this occur only once in their series of fifteen hundred cases. Contrary to the opinion held by some, the Mayos do not think it wise to remove a functionating gall-bladder unless there is a direct indication present. If a cholangitis exists, the gall-bladder affords a ready means of drainage, especially in common-duct cases, for these often require a secondary operation. When there is future contraction and obstruction of the common duct, the organ also constitutes a safe guide to the deeper structures. The permanent results were almost uniformly good after this operation and the disability brief.

Among the 319 cholecystectomies the mortality was 3.13 per cent. Although this operation has an increasing field, its greater risk constitutes, according to the writers, a valid excuse for not using it to replace cholecystostomy. When the gall-bladder is easy of access and the disease is confined to this organ, cholecystectomy may be regarded as the operation of preference, even when the simpler operation would have answered the purpose; but when the patient is obese and the organ adherent, the operation at once becomes more dangerous and difficult. The cure in these cases is, of course, absolute when the disease has been confined to the gall-bladder and the operative disability was slight.

Common-duct cases, numbering 207, were accompanied by the highest mortality, as might be expected, the death rate varying, depending on the type of the disease, from 2 to 34 per cent. An interesting complication in connection with this class of operation is involvement of the pancreas, and in eighty-six out of the total number of the cases, this organ was involved to an appreciable extent, but the writers believe that unless the inflammation is obstructive, it has no decided influence on the prognosis of the individual case. In summing up the causes of the sixty-six deaths, it will be found that 15 per cent. were accidental and could not be prevented. The largest number were due to cessation of liver function, usually the result of infection, and next came exhaustion due to chronic cholemia.

The lesson to be drawn from these statistics is that which has also been found to be true in other conditions. The great mortality which attended the early operation for appendicitis could not be ascribed to the operation, but rather to the fact that it was not carried out until the disease had gone beyond the appendix. Mayo rightly concludes that in gall-stone disease we must operate early, before the process extends beyond the gall-bladder, when the mortality is considerably less than 2 per cent., even with the deaths from accidental causes included. When the stone has passed into the common duct, the disease is no longer localized, but there is the added danger of hepatic infection and cholemia, and the possibility of malignant disease.

BERIBERI OR ALCOHOLIC NEURITIS?

THE considerable number of cases of beriberi which have been reported since our advent in the Far East has furnished a source of anxiety to the medical authorities of both the army and the navy; for it has been found that Americans are apparently not immune to a disease which at first was believed to attack only the native population, and numerous instances are recorded in which officers and enlisted men stationed in our Eastern possessions have become the victims of this malady. The disease is essentially a neuritis, and as it varies greatly in its individual features and is therefore by no means a uniform complaint, the exact diagnosis is apparently surrounded with some difficulties. It has become an unfortunate habit with the laity, and to some extent among medical men, to include within the designation of some new or "popular" disease, many cases which on closer scrutiny fail to meet the necessary specifications. One is impressed with this fact upon reading an article by J. S. Taylor in a recent number of the *Journal of the Association of Military Surgeons* (June, 1906), in which the writer claims as the result of an experience gained by several years' residence in Eastern countries, where beriberi is endemic, that many instances of nerve affection attributed to this disease are cases of multiple neu-

ritis due to a variety of other causes, among which alcohol is probably the most frequent.

The germ of beriberi, if there be one, has no doubt been assumed to be the etiological factor in many cases of neuritis occurring in persons residing in those countries where the disease prevails. The mistake may have been an honest one, for the symptoms are often identical, but in other cases convenience has probably dictated the diagnosis, particularly in individuals in whom another cause would be more unpleasant and less heroic. The fact should be borne in mind that beriberi is apparently absolutely dependent upon hygienic conditions and is favored by unsanitary surroundings. Alcoholic neuritis, on the other hand, is entirely independent of these factors. Taylor's experience has shown, moreover, that in the army the majority of the so-called cases of beriberi were among the officers, who made no pretense to total abstinence, and those of the enlisted men who were affected were invariably hard drinkers. Cold, exposure, and exhausting conditions may bring on a neuritis, and not every case wrongly called beriberi is necessarily alcoholic, but these are instances of neuritis pure and simple and dependent only remotely on the local conditions or on climate in the sense that true beriberi is. Officers who acquired what in the writer's opinion was alcoholic neuritis, belonged to all grades and performed the most varied duties under the most dissimilar circumstances, the only constant feature in every instance being that the victim indulged in alcohol in some measure; and this indulgence was probably in excess of the narrow limits of safety which are demanded by the tropical climate, for the baleful influence of the latter in lowering the tone and vigor of the system, while perhaps calling for the stimulus of a moderate amount of alcohol, no doubt increases the harm of consuming alcoholic beverages to excess.

As the writer truly states, there is a glamour of romance thrown about an individual who has been compelled to reside in the tropics and thus become the victim of what may in charity be called an attack of beriberi. Less sympathy would, no doubt, be extended if it were known and admitted that the true cause of the disturbance was the cup that cheers, and the recovered subject of an attack would not point with pride to the horrors which he had gone through in the path of duty. It has long been maintained that the abuse of alcohol in the tropics constitutes a peculiar menace to the health of those who may be compelled to reside there, and here we have apparently another bit of confirmatory evidence in support of this contention. It is to be hoped that Dr. Taylor's suggestions will prompt a closer investigation of these cases which are conveniently labeled by a name which fails to account for their true origin, even if the truth has a less agreeable aspect.

TUBERCULOSIS.

In the Section on State Medicine of the British Medical Association, at the meeting just held in Toronto, a long and more or less interesting discussion was held on Tuberculosis. Medical men from all parts of the world expressed their views on various phases of the malady, and among those men were many from this country.

The paper of Dr. George Homan of St. Louis was particularly suggestive. The paper was on the influence of domestic methods and household dust on tuberculosis. The point was emphasized that hotels, clubs, and offices are a source of danger to the community in that their internal arrangements frequently render them to a great extent fertile breeding grounds of tuberculosis. The ornamental and luxurious fittings and the heavy carpets and hangings which are generally features of such establishments are convenient harbors for dust, and the so-called cleaning which takes place daily as a rule simply stirs up the dust and does not get rid of it. The author of the paper gave some examples which had come under his immediate notice of the careless manner in which clubs are managed. The lavish expenditure of money in making clubs, hotels, and offices appear luxurious is more than money wasted; it is money put to a bad purpose. Many private houses are in the same category, but reforms in this respect should be initiated in those establishments to which the public has ready access and which certainly should not be the ones to sacrifice health to outward show. All such establishments should be subject to sanitary inspection.

Dr. Probst, Secretary of the Ohio State Board of Health, read a paper entitled "Some Doubtful Phases of the Tuberculosis Question." The whole trend of the paper was interrogative. It was asked if cattle are known to be tuberculous whether these should be slaughtered on a wholesale scale; whether persons suffering from pulmonary tuberculosis should be isolated; how sweat-shops should be effectively dealt with; to what degree the use of alcohol predisposes individuals to the contraction of consumption; should preventive measures be in the direction of destroying the seeds of the disease, or should they attempt so to build up the system by good food and by effective sanitary measures as to render the afflicted person able to withstand the attacks of the malady? Of course we should all like to know the true answers to these very pertinent questions, but it is idle to hope for universal agreement, perhaps, upon any one of these points. The majority of physicians, however, are of one mind in regard to the broad principles concerning pulmonary tuberculosis. It is now a matter of common knowledge that environment plays the most important rôle in originating and in spreading the disease. Heredity may induce a susceptibility in the individual to the malady and may provide a suitable breeding place for its germs; such predisposition is latent and becomes a factor in the production of the disease only when other conditions are favorable. The person born of tuberculous parents who lives a healthy, rational life stands a better chance, on the whole, of reaching a green old age than does he whose parents and ancestors had no tuberculous taint, but who has lived in a way calculated seriously to injure his health. The latter has, by lowering his vital powers, laid himself open to the attacks of the disease. As a means of prevention as well as of cure, the writer urged that every one, whether tuberculous or not, should whenever possible sleep out of doors.

As to the part played by milk and alcohol in the production of pulmonary tuberculosis, opinions at the meeting differed widely. While some held that both milk and alcohol were potent factors in disseminating the tubercle germs among the human race and in preparing the soil for their reception, others were of the opinion that these substances might almost be termed negligible quantities so far as the production of pulmonary tuberculosis was concerned. One speaker stated as his opinion that milk and alcohol were only in a small degree responsible, but took the view that indolent breathing as a cause of consumption was universally overlooked. All present were unanimous in the belief that educating the public was one of the best means of successfully solving the tuberculosis problem. This is undoubtedly true; indeed, it is actually too obvious to need emphasis.

A New Use for Babinski's Reflex.

The peculiar reflex phenomenon to which Babinski's name has been attached has often been noted in organic nervous diseases, especially when the pyramidal tracts are involved. The symptom has been described as a slow extension of the great toe when the sole of the foot is irritated, without any previous plantar flexion such as we find in the normal individual. Although it seems to be invariably present in children, it can only rarely be elicited in normal adult individuals. The reflex has been quite generally accepted as a diagnostic feature in lesions of the pyramidal tracts, and it has also been found in epilepsy, meningitis, and various comatose states, and, strangely enough, also after scopolamine injections, whether these were employed for their general sedative or their anesthetic effect. Although noted, there has apparently been no effort made to account for this phenomenon, and a recent contribution on this subject by Link (*Zeitschrift für klinische Medizin*, Vol. 59, Nos. 2, 3, and 4) should therefore prove of interest. This observer found the Babinski reflex present in 37 out of 43 patients to whom scopolamine had been administered, even when a dose as small as 0.0004 had been injected. Link believes that the phenomenon in question is due in these cases to a functional shutting out, as it were, of certain portions of the cerebral cortex. The appearance of the reflex is, therefore, a sign that the scopolamine has become effective, but it should not be regarded as an evidence that the narcosis thus induced is sufficiently deep to take away entirely the sense of pain. It seems, therefore, that although the practical application of Link's observations is limited, it may be of some value within certain bounds.

The Etiology of Paroxysmal Tachycardia.

Although this condition has long been recognized as a clinical entity, we are still very uncertain as to its etiology, and many speculative theories have been advanced to account for the phenomenon. When a lesion of the heart exists, it is but natural to assume that the latter is the cause of the symptom, but in many instances no deviation from the normal can be detected in this organ, either during life or at the time of the autopsy. A connection between this form of cardiac palpitation and some disturbance of the nervous system has been claimed to exist by a number of writers, and this view seems confirmed by the report of two cases by Reinhold (*Zeitschrift für klinische Medizin*, Vol. 59, Nos. 2, 3, and 4), in which it was possible to trace the relation of the tachycardia to a lesion of the central nervous system which involved the cardiac centers. In the one case the autopsy revealed the presence of a syphilitic basilar meningitis, with a localized arteritis of the vertebral and basilar arteries, which undoubtedly brought about circulatory disturbances in the medulla oblongata. In the other case there was present a tumor in the left cerebral hemisphere which probably served as a source of reflex irritation and affected the cardiac inhibitory centers in the bulbus. This report is of considerable interest, as it affords an apparent confirmation of a theory which has been expressed by a number of writers in the recent literature of the subject.

Sunday Risks.

We wonder if the officials whose duty it is to look after such things are aware of the criminal overcrowding every Sunday of the boats carrying pleasure seekers in the waters of New York. If they are not, it is because they are neglectful of their duty; if they are, they are even more culpable in not putting a stop to the abuse. On a recent Sunday evening, for example, one of the boats returning from down the bay was so packed with men, women, and babies on each of its three decks that it was absolutely impossible to move about, and where one was placed there he had to remain until the boat reached its pier. Had anything occurred to start a panic, nothing could have prevented a frightful loss of life, and had a fire started or a collision occurred, the *Slocum* disaster would have been as nothing in comparison. And this condition was doubtless the same in nearly every boat going to and from the beaches. Sunday is the day of fatalities—twelve young men and one child were drowned in New York on a recent Sunday, and seven more were killed by automobiles, bicycles, and runaway horses—but some day the twenty deaths will be multiplied by one hundred if the overcrowding of boats continues to be permitted. How to accommodate the hundreds of thousands of seekers after fresh air every pleasant Sunday is doubtless a problem, but if all cannot be transported without the fearful risks to which they are now exposed, some must be forced to stay at home or turn in other directions.

News of the Week.

Butchers and Bakers in Prussia.—The "jungle" has been found in England, France, Japan, and indeed all countries where a search has been made for it, and America, so far from being the worst or only sinner against packing-house hygiene, is now shown merely to have been the first to expose and correct the evil. One of the latest to investigate home conditions and to find them bad is Prussia. A dispatch from Berlin says that the Government Medical Department has issued a report on the sanitary condition of the Prussian bakeries and slaughter houses in which it is set forth that many of the butchering establishments were found to be in a very unclean condition. Some of them were situated in dark cellars, where cleanliness was impossible, and others had no facilities for the employees to wash themselves. The Government Inspectors found the conditions in the bakeries to be particularly objectionable. In one town boys kneaded the dough with their feet, and one bakery was found to be occupied by cats and hens. In another town a baker's oven served *ad in-*

terim as a goose pen. One baker admitted that his floor and vats were scrubbed only once a year.

Sanitation of Restaurants.—The Commissioner of Health of Chicago, Dr. Charles J. Whalen, in the weekly bulletin of the Health Department for August 18, says: "Of not less importance than rigid inspection at the slaughter house and in the market is the sanitation of the restaurant and the limitation of cold storage. There are no doubt many clean restaurant kitchens, but there are also a great many which have no suggestion of cleanliness or sanitation, and this is especially true in a large city like Chicago. With a view of bettering the sanitary conditions and protecting the people from consuming unwholesome food, the municipal authorities ought to license all places where food is cooked and consumed, and such an ordinance should be vigorously enforced by parties under whose jurisdiction it is placed. There is a wide field for improvement in Chicago along the lines herein suggested; yet this improvement ought to be easy; for when it becomes known that certain restaurants are worthy of public patronage because of their sanitary conditions, they will be likely to get the patronage, to the disadvantage of those which are not under such conditions."

Trachoma in Immigrants. — Four immigration inspectors sailed last week to determine the cause for the great increase of late in the number of cases of trachoma among immigrants. For sixty days prior to August 4 the Department of Commerce and Labor had assessed in fines on steamship companies $8,100 for bringing into this country diseased aliens, most of them suffering from trachoma. For every case proved against the steamship companies a fine of $100 is collected, and the companies are compelled to return the diseased immigrants to the port of embarkation. It is believed that the fault lies with the system of health inspection at the ports of departure.

The Microbe of Whooping Cough.—The correspondent of *The Sun* in Antwerp says that Dr. Gengou of the Belgian Royal Medical College reports the discovery of the whooping cough microbe. It is said to resemble Pfeiffer's influenza bacillus.

The Proposed Pollution of New York Harbor.—On Friday of last week a special meeting of the Board of Aldermen of Paterson was held to receive the report on the sewage disposal question. Mayor Johnson was authorized to appoint a committee of forty-eight to confer with a committee from Newark. It is reported that Paterson is now inclined to favor the trunk sewer, provided there is no legal obstacle to the discharge of the sewage into New York Bay. It is to be hoped that such legal obstacle may be found and found speedily.

Dr. Maximilian Herzog has been appointed pathologist to the Michael Reese Hospital, Chicago. Dr. Herzog was for several years stationed in the Philippines.

Missouri State Sanatorium. — The cornerstone of the Missouri State Sanatorium for the treatment of tuberculosis was laid by Governor Folk at Mount Vernon on August 15.

A Sanatorium for Stoughton. — An association has been formed at Stoughton, Mass., for the purchase of land and erection thereon of a sanatorium for the treatment of tuberculosis. A site has already been purchased on high ground, the highest between Narragansett Bay and Boston, and it is purposed to build on it a model institution, to cost $100,000.

Unable to Provide a Prison with a Tuberculosis Hospital. — The Attorney-General of Tennessee has given an opinion that the proposed erection by the Prison Commissioners of a tuberculosis hospital at the main State's prison would be illegal under the terms of the present prison act. The Governor will recommend in his message to the next Legislature that the necessary authority be given. There are now about twenty-five consumptives in the prison, and hardly ever a less number. Often such convicts are pardoned mainly because they are a menace to other prisoners.

Rapid School Inspection.—In accordance with a law passed by the Massachusetts Legislature, all the school children in the State will be regularly examined by physicians appointed by the local Health Boards. In Fall River, with a school population of 21,000, twelve inspectors have been appointed, and they will be required, it is stated, to complete the preliminary inspection of the public and parochial schools during the three school days of the first week of the fall term.

A Victim of Christian Science.—Five fanatics were censured in a verdict rendered by a Rochester coroner last week on the death of a young woman from meningitis. This girl was ill eleven weeks and was attended only by so-called Christian Science "healers," their treatment consisting of prayer and endeavoring to impress upon the mind of the girl that she was not ill, and if she but realized she was "the ideal child of God" her illness would be overcome and she would be well. The coroner recommends that the Health Bureau proceed against these "healers" under a city ordinance for neglecting to report an infectious disease.

Ticks and Spotted Fever.—Dr. King of the U. S. Public Health and Marine Hospital Service, who has been in Montana studying the manner of infection of spotted fever, states that he has confirmed the theory of the agency of ticks in transmitting the disease, having succeeded in inoculating animals in this way.

The Piscataquis County (Me.) Medical Association held its annual meeting at Dover on August 16. The following officers were elected for the ensuing year: *President,* Dr. C. C. Hall of Dover; *Secretary,* Dr. C. W. Ray of Sangerville; *Treasurer,* Dr. E. A. Thompson of Dover; *Executive Committee,* Drs. R. H. Marsh of Guilford, Hiram Hunt of Greenville, and Daniel Hayes of Henderson.

Cumberland Valley Medical Association—The fourth annual meeting of this association will be held at Chambersburg, Pa., on September 4, 1906, under the presidency of Dr. James Evelyn Pilcher of Carlisle, Pa. The secretary is Dr. John J. Coffman of Scotland, Pa.

American Roentgen Ray Society.—The seventh annual meeting of this society was held this week at Niagara Falls, under the presidency of Dr. Henry Hulst of Grand Rapids, Mich.

American Electro-Therapeutic Association. — The sixteenth annual meeting of the American Electro-Therapeutic Association will be held at the College of Physicians, Philadelphia, September 18, 19, and 20, 1906, under the presidency of Dr. William Benham Snow. Fellows and others intending to be present are requested to secure certificate of the railroad agent at the point of departure in order that the cost of transportation may be at the rate of a fare and a third. The headquarters of the association will be at the Hotel Flanders, Fifteenth and Walnut streets.

Tri-State (Alabama, Georgia, Tennessee) Medical Society.— The eighteenth annual meeting of the Tri-State Medical Society of Alabama, Georgia, and Tennessee will be held at Chattanooga, October 2 to 4, 1906. Reduced rates have been obtained

from all points in Alabama, Georgia, Tennessee, Mississippi, Louisiana, and Florida, and an unusually large attendance is looked for. It is hoped that this society will form the nucleus of a branch of the American Medical Association, to be called the Association of the Southeastern States, and recommendations to that effect will be made at this meeting. Physicians desiring to read papers should send their titles at once to the secretary, Dr. Raymond Wallace, Chattanooga, Tenn.

Obituary Notes.—Dr. Joseph W. V. R. Plummer of Key West died August 9, after an illness of several weeks. He was born in Baltimore, March 17, 1842, and was graduated from the Southern Medical College, Atlanta, in the class of 1884. He served a term as Mayor of Key West and at the time of his death was city health officer.

Dr. James Brown Coombs of Washington, Iowa, died August 13, at the age of eighty-one years. He began the practice of medicine in 1851 and retired in 1891.

Dr. D. L. Delk of Oakdale, Tenn., died August 11. He was a graduate of the Chattanooga Medical College in the class of 1897.

Dr. William A. Bliss of Brooklyn died August 19. He was born at Sandlake, N. Y., in 1841, and was graduated from the Albany Medical College in 1866. He then moved to Brooklyn and took up the practice of his profession. In 1893 he moved to Fishkill, but again returned to Brooklyn in 1899.

Dr. John Gregg of Clarksburg, W. Va., died August 19, at St. Mary's Hospital in that city. He was born in Preston County, W. Va., May 27, 1838.

Dr. George D. Hamilton of Jackson, Tenn., died at St. Joseph's Hospital, Memphis, on August 16, aged thirty-five years. He was a graduate of the Medical Department of the University of Nashville in 1899.

Dr. Alvah B. Dearborn of Somerville, Mass., died August 19, at the age of sixty-four years. He was born in Topsham, Me., and was graduated from the Bowdoin Medical School in the class of 1870. He practised for a time in Newburyport before going to Somerville.

Dr. J. A. Slaughter of Kentuck, Va., died, after a long illness, on August 16, at the age of seventy years. He was born in Campbell County and had been in active practice for nearly fifty years.

Dr. C. B. Raines of Americus, Ga., died August 16. He was born in Fairfield County, S. C., and was graduated from the Louisville Medical College in 1871.

Dr. J. W. Breedlove of Fort Smith, Ark., died August 16, at the age of eighty years. He was born in Virginia in 1827 and was graduated from the Medical Department of Tulane University in 1849. He served throughout the Civil War in the medical corps of the Confederate Army. He was a resident of Fort Smith for forty-five years.

Dr. Charles Macmanus of Matamoras, Mexico, died August 14, at the age of eighty-six years. He was born in Ireland, but came to this country soon after graduating in medicine. He was surgeon in the U. S. Army during the Mexican War, and soon after peace was declared established his home in Matamoras.

Dr. Reginald J. Fitzgerald died August 19, at his home in Minneapolis, aged forty-six years. He was born in Nicaragua and was graduated from the Albany Medical College in 1882. He began practice that same year in Minneapolis. He was surgeon-major in the Thirteenth regiment of the Minnesota National Guard.

Dr. John A. Rice of Merton, Wis., died on August 19, at the age of seventy-five years. He was born in Essex County, N. Y., and was graduated from the Medical Department of the Western Reserve University, Cleveland, 1851.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY FUND—SCIENCE ASSOCIATION—NOMENCLATURE OF DISEASES—AMALGAMATION OF SOCIETIES—SCHOLARSHIP FOR STUDYING RHEUMATOID ARTHRITIS—TWO EXTRAORDINARY FATALITIES—OBITUARY.

London, August 10, 1906.

At a meeting of the Hospital Sunday Fund the report of the Distribution Committee was adopted and thanks accorded to all who had assisted. The collections amounted to £56,303, to which a legacy of £3,000 is to be added. The Cancer Hospital did not receive an award, as it is not in great want of funds, but the committee stated they fully realized the excellent work carried on in it. The award to Charing Cross Hospital is not to be paid until the effect of the special appeal is seen. Dr. Glover called attention to the enormous out-patient attendance at the London Hospital, suggesting that some limit should be placed upon it. The Hon. Sydney Holland replied that the reason the patients were so numerous was that it was the only hospital in the East End. He assured the meeting that all the cases were inquired into and that there was no abuse of the hospital by out-patients. That is Mr. Holland's opinion, which differs *in toto* from that of the profession, who regard Mr. Holland as to blame for the pauperization caused by those doings.

The Congress of Scientists at York has excited, I think, less interest than usual among the public, though some of the subjects might have been expected to give rise to animated discussions.

Professor Francis Gotch, in the Physiological Section, made a lively attack on the neovitalists, who, he declared, were prepared to state that certain physiological phenomena were, from a physical and chemical point of view, inexplicable and must forever remain so. Neovitalism, like its parent, vitalism, was fostered by the imperfect and prejudiced view of man as to his own existence. Unwilling to think his material part only differed in complexity from that of the nonliving world, he fabricated out of his own conceit a special realm. In 1898 Professor Japp, in the Chemical Section, made the sweeping statement that "no fortuitous concourse of atoms, even with all eternity to clash and combine, could compass this feat of the formation of the first optically active organic compound." Professor Gotch condemned as "unscientific" the notion that any physiological phenomenon was caused by vital force or was an argument for "vitalism." Such views only prejudiced scientific study. But neovitalism had, he said, "lost its corrosive character of late; its obstructive viscosity was continually yielding to the accumulating mass of more precise knowledge which it endeavored to obscure." I commend to you this sentence of the professor's denunciation, which went on to talk of those who are the "prey of verbal mystifications."

In the Physical Science Section Mr. Ladenburg reported that he had detected a new gas by allowing liquid ozone to vaporize into a vacuum tube: it seemed to be a modification of oxygen and had a higher molecular weight than ozone. Sir W. Ramsay and W. Spencer described chemical and electrical changes caused by ultraviolet light which point to the conclusion that elements and compounds when illuminated discharge corpuscles.

There were other subjects deserving of reports, did space permit. Of course, radium came in for much attention in various directions. The facts restated and the speculations about it, I understand, attracted both the public and the scientists. The latter, after their calculations about the cooling of the earth and the sun and the hypothesis that *if*—a rather strong *if*—so much radium were present, all suppositions as to the loss of heat would be upset, had a fresh surprise sprung upon them when Sir W. Crookes announced that he had made an experiment which proved that ice melted no faster near radium than near indifferent matter.

At the Royal College of Physicians on the 26th ult. the chairman of the Classification Committee, Dr. Pye-Smith, reported that the fourth edition of the "Nomenclature of Diseases" was completed, and spoke of the great assistance of various gentlemen, especially of the secretary of the committee, Dr. Ormerod, and of Mr. Shattock, who had prepared the Latin translations. A vote of thanks was accorded to Dr. Pye-Smith, and Dr. Ormerod was asked to

accept an honorarium of 200 guineas. Outside assistance has been given by the president and fellows of the College of Surgeons and also by the sister colleges in Scotland and Ireland. It will thus be seen that the "Nomenclature" is an authoritative work and the college, by revision, is keeping it abreast with the advance in medical science and practice. It is gratifying that as little deviation as possible, as at first intended, from the terms employed in the Register-General's office, is a point still kept in view.

In this revision the Section of General Diseases has been divided into (1) infective diseases, (2) intoxications, (3) general diseases not included in the foregoing, (4) morbid conditions in various parts. Pneumonia now takes its place in the first, epidemic diarrhea becomes "infective enteritis," membranous croup and membranous laryngitis are no longer to be applied to diphtheria, a decision which reminds one of a rather obstinate discussion as to these terms. "Pyrexia of uncertain origin" displaces fibricula and simple continued fever. Puerperal fever is dismissed, and pyemia, septicemia, or septic intoxication qualified by the adjective puerperal is to be used. In smallpox cases the presence or absence of vaccination marks should be noted, and when present their number, size, and character. Further information of a trustworthy nature should be added as to whether the patient was vaccinated or not, if so when, and further if revaccinated. The terms strumous and scrofulous are discarded. Intoxications include cocainism, ergotism, metallic poisoning, and tobacco poisoning. In the third group are anemia, cretinism, diabetes mellitus, exophthalmic goiter, gout, myxedema, purpura, rickets, scurvy, etc. In group 4 are malformations, the effects of certain parasites and poisons, new growths. The committee discourages names indicating merely symptoms, as convulsions, apoplexy, etc., whenever it is possible to state the cause. Such cases should be registered under the head of the primary disease, the secondary affection being added.

The movement for amalgamating the various medical societies is progressing, slowly but steadily. The organizing committee appointed a year ago recommends that eighteen societies should become the sections of the new union, with the hope that two others will be formed at an early date. All male members of societies joining in the union on its formation are to be admitted without election: female members of a society taking part in the amalgamation to become members of that section. Each section will be, as far as possible, self-governing and be represented on the council and the editorial committee. The finance committee of the general council is to control the expenditures of the sections. The general council of the union is proposed to consist of the president, the presidents of sections, two treasurers, two librarians, two secretaries, and eight other fellows.

A scholarship of £150 for two years for the investigation of rheumatoid arthritis has been placed at the disposal of the Cambridge University's Committee on Special Diseases. Dr. R. C. Brown of the Preston and Lancashire Infirmary is the donor, and the scholarship will be named after him.

Two remarkable fatalities occurred this week. As a Leicester family was picknicking at a neighboring village one of the children dropped an empty ginger beer bottle, which fell on a full one and caused it to explode. A piece of the glass struck his little brother's neck and penetrated the jugular.

The other extraordinary accident is reported this morning. While a gentleman of 57 was putting sticks to chrysanthemum plants in his garden one of the sticks broke off short in his hand and he fell forward onto another stick, which pierced his right eye and penetrated the brain.

Deputy Surgeon-General H. F. Smith died on Sunday, aged 82. He took his M.R.C.S. in 1846 and M.D., Aberdeen, in 1850. He served through the Eastern campaign, 1854-5, being attached to headquarters, and was not absent from duty one day in that period. He had medical charge of the staff, was present at Alma, Balaclava, Inkerman, and throughout the siege of Sebastopol; received the medal, four clasps, the Turkish medal, and the Medjedie. He retired in 1875.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

PAROXYSMAL ASTASIA—CONGENITAL ELEPHANTIASIS OF THE PREPUCE—NERVOUS STRICTURE OF THE CARDIA—IDIOPATHIC RENAL HEMORRHAGE.

VIENNA, July 31, 1906.

In the clinic for nervous diseases at the University, Erben has under observation a patient suffering from a peculiar form of astasia following an injury. Ordinarily the patient is able to stand alone and walks with a firm step, but when he becomes excited he begins to tremble and standing is interrupted by dancing steps (clonus), and in from a quarter to half a minute he is no longer able to stand, but must run forward with tripping steps and stiff legs in order not to fall. There are no automatic movements of balancing, but merely a tripping in the direction in which the patient feels that he is about to fall. Here then is a morbid picture composed of two factors, of the clonic spasms coming on in the form of attacks and of the impossibility of regaining in the usual way the equilibrium thereby upset. These two symptoms form the complex astasia described twenty years ago by Blocq.

Heinrich Lehndorff has reported an interesting case of congenital elephantiasis of the prepuce. The child, now sixteen months old, was found, after a normal pregnancy on the mother's part and easy delivery, to be suffering from an extensive non-painful edema of the external genitals and neighboring parts. The penis was the length and thickness of a finger and bent upwards, and the prepuce was greatly lengthened and thickened, of a doughy consistency, the skin being unchanged. The inguinal glands were not enlarged. The urine of both child and mother was free from albumin. The swelling of the scrotum and lower part of the abdomen gradually subsided in the course of six weeks or so, but the thickening of the prepuce persisted. This is now 2 cm. in length, markedly thickened, but there is no new growth palpable, and there is no vascular dilatation. The case was diagnosed as one of congenital elephantiasis of the prepuce.

Emil Schwartz reports a case of purely nervous closure of the cardia resulting in a marked fusiform dilatation of the esophagus. The beginning of the affliction dated back thirty years, during all of which time there had been dysphagia with vomiting of most of the food taken, resulting in extreme inanition. The psychic element was most marked. The patient could eat absolutely nothing in company without immediate regurgitation, and it was only in the solitude of her own apartment that she could, with great difficulty and in pain, swallow enough to support life. The patient was finally sent to the seashore for a change of air and scene, and from the very first day of her arrival was able to eat a dinner of several courses, even in the public dining room, and since that time, with a few periods of relapse of short duration, the cure has persisted, and the patient has gained notably in weight.

Illyor recently operated in a case of essential hemorrhage from the kidney. The patient, a man 44 years old, had some two years ago passed bloody urine for ten or twelve days. In July of this year, after a period of severe labor, the urine again became bloody, and the bleeding persisted Cystoscopic examination showed the origin of the hemorrhage to be from the left ureter. Examination, both chemical and microscopical, of the urine collected by ureteral catheterization, showed that the urine from both kidneys was absolutely normal. Although the examination was negative, as the bleeding continued, the left kidney was exposed. Its surface was smooth and it was of normal consistency. It was laid open from one pole to the other, the incision extending into the pelvis, but no pathological changes were found; neither was anything abnormal found in a thin section secured for microscopical examination. The incision was closed with four button sutures and the organ was replaced. The blood disappeared from the urine in three days and has not since appeared. The patient has gained in weight, has no cough and no elevation of temperature, and seems and declares himself to be perfectly well

AN ENGLISHMAN'S IMPRESSIONS OF THE TORONTO MEETING.

(From an Occasional Correspondent.)

TORONTO, August 21, 1906.

Toronto is assuredly one of the most beautiful cities of the world. Its position is almost unrivaled, and man has not, as in the case of Quebec, done his worst in regard to buildings. But in the matter of clean streets Toronto weighed in the balance would be found wanting. This fact is fully recognized by its lay press, one of its leading daily papers of August 21 containing an editorial headed "Our Disgraceful Streets." With this one drawback, Toronto has charmed all its medical visitors. And what a crowd of English-speaking doctors are here gathered together! From almost every part of the vast British Empire they have come. There are representatives from New Zealand, from Australia, from Africa, from the West Indies, and from India and the far Eastern possessions. A feature of the meeting which forcibly strikes the Britisher is the large number of physicians from the States who have put in an appearance. The *Daily Journal* of August 22, issued by the British Medical Association, publishes a list of more than 400 Americans from across the line who are here, while there are undoubtedly many who have yet to register. Canadian

and British medical men at present number considerably over 1,000 and include many of the leading lights of the British medical profession. It is needless to dwell upon the fact that such a commingling can be productive of nothing but good, whether regarded from the standpoint of medical science or from the political point of view. Americans can learn much, as regards medical science, from the steady, reliable, conservative Britisher, who always looks before he leaps, and the Briton can learn much from the more impetuous and perhaps more brilliant American.

A better situation than the magnificent medical buildings of Toronto University could hardly be imagined. The buildings themselves, ample, airy, and well ventilated, are splendidly adapted to the purpose. The main building, a picturesque structure, is devoted to the offices and to the official work of the association, and to writing rooms, resting rooms, and the many conveniences required by a meeting of the size of the present one. The whole *mise en scène* is in a high degree an attractive one, and appeals to an Englishman by reason of its freshness. It is unlike anything to be seen in Great Britain.

The opening ceremony in Convocation Hall on August 21 was eminently distinctive. A quarter of an hour before the ceremonies inside the building commenced all the delegates and the distinguished visitors, arrayed in cap and gown, assembled in the University Quadrangle and, under the leadership of the retiring president, Dr. Franklin of Leicester, marched to the Convocation Hall. The delegates were a mass of color, some of them indeed gorgeous, and included in their number were two Indian medical men, one of whom, from Bombay, was clad in native Parsee costume. A large assemblage had gathered in the hall, among the number being many ladies and many of the prominent personages of Canada. Sir James Grant of Ottawa, for many years physician to Governor-Generals of Canada, was present. Among notable British medical men upon the platform were Sir Thomas Barlow, Sir Victor Horsley Sir James Barr, Dr. Donald V. MacAlister, Dr. Clifford Allbutt, and Dr. Rose Bradford.

The proceedings were opened by Dr. Franklin, the retiring president, who delivered a valedictory address. It was very similar to the usual run of such addresses and was given in a hearty and genial manner. The speaker referred to the good work done during the past year by the medico-political and ethical committees, and he gave unstinted praise to Toronto itself and to the hospitality of its inhabitants. The president-elect, Dr. Reeve, Dean of the Medical Faculty of Toronto University, was then introduced to the delegates and invested with the gold badge of his office. Indeed, the usual routine of such meetings was decorously and properly gone through with, the only incident of especial note which occurred being the manifestations of the popularity of Sir Victor Horsley, attested by the acclamation when he was made a vice-president for life of the association. Sir Victor, who is a pleasing and distinctive speaker, and who looks the strong personality that he is, made an effective speech in returning thanks for the honor done him. The president-elect made a lengthy speech, much of which was taken up in panegyrics of medical men, alive and dead, of many countries.

On the evening of the 21st Dr. W. S. A. Griffith delivered an address in Obstetrics in the Convocation Hall. The address covered a large field and was characterized by sound common sense. On the afternoon of August 22, in the Convocation Hall of Toronto University, Sir James Barr of Liverpool delivered the address on Medicine. The subject was a very technical one, but enlivened at intervals with humorous and witty remarks. There was a good audience, including many ladies and some children, but as the address was in many parts incomprehensible to several of the medical men present, it is difficult to understand what pleasure it could have given to the first named. Sir James Barr indulged in some sharp epigrams; for instance, he said no amateur should be trusted with the repair of the circulation, yet thousands of American and British men and women poured yearly into their stomachs tons of baneful drugs, simply upon the advice of perfectly ignorant people. Again he remarked that a life of idleness and luxury is more deleterious to the arteries than is the work of a navvy. The happy mean is the object at which to aim. Sir James, who is the typical Scotchman, with a remarkably strong Scotch accent, possesses a pawky humor and must have made the many Americans present wonder whether they had not misjudged the Scotchman so far as the possession of this gift is concerned. A vote of thanks to Sir James Barr was moved by Dr. Donald MacAlister of Cambridge University, who again must have confounded the Americans, for his speech fairly bristled with witty and good things. The vote of thanks was seconded by Sir William Broadbent, who took occasion in a good-humored way to criticise some of Sir James Barr's conclusions. They hold somewhat opposite views in regard to the circulation.

So far as the meeting has gone it has been a great and unqualified success. There are present both quantity and quality, and the hospitality of the inhabitants of Toronto is profuse.

Progress of Medical Science.

New York Medical Journal, August 18, 1906.

The Present Status of the Treatment of Appendicitis; the Family Physician's Responsibility.—R. C. Coffey's paper on this subject is largely statistical, and he indulges in some theoretical speculation for the purpose of approximating the prevalence of appendicitis and the relative results of medical and surgical treatment. There seems to be no reason why cases diagnosed and referred to a competent surgeon within the first twenty-four or forty-eight hours should not present a mortality almost as small or at most less than two per cent. Almost all the deaths in the hands of well trained abdominal surgeons are the result of: 1. The family physician failing to recognize the disease early. 2. The family physician temporizing with medication or the Ochsner treatment. 3. The inability of the family physician to procure a competent surgeon early. 4. The opposition of the members of the family to surgical treatment. The duty of the physician, therefore, is first to acquire a realization of the fact that appendicitis is the most frequent of all the serious abdominal lesions; that many more cases of the dyspepsias, cramps, and acute peritonitis cases than have been formerly suspected are appendicitis. He advises the course proclaimed by Kelley: "The first indication in appendicitis is to call in a surgeon." The surgeon should determine the necessity for an operation.

Value of the Bier Treatment.—Edward Adams believes that the rubber bandage has, in a great many instances, superseded the knife in the treatment of various acute and chronic conditions. This method of Bier is of great assistance if properly used, and dealing especially with acute surgical affections of the soft parts.

Journal of the American Medical Association, August 25, 1906.

The Treatment of Emaciation.—L. Breisacher finds that leanness may be due to various causes. It is sometimes apparently hereditary, but may arise as a primary or secondary condition. The one great cause, excluding certain emaciating chronic diseases, is insufficient amount of food which may be due to loss of appetite from physical or mental causes, or the result of faulty dietetic habits which are sometimes handed down in families from generation to generation. Frequently, it results from an ignorance of the nutritive significance of particular foods or is the effect of eating but one or two meals a day in persons not fitted for such a régime. It may be due to poverty or nervousness, sexual neurasthenia or hysteria. These latter predominated, together with digestive abnormalities in the majority of his cases, and he has also observed attendant arteriosclerosis and insomnia, which are given by Cabot as causes, in a number of his cases. To a second group of causes belong the gastrointestinal disorders, mechanical or secretory, which he observed in nearly all his patients. He thinks that there is no doubt that the foundation of these disorders is often laid in the artificial feeding of infants. He also mentions the improper metabolism of food and increased oxygenation in the blood which cannot be precisely defined. In the treatment, therefore, it is advisable to make thorough examinations for all possible conditions, and to ascertain to what degree the stomach and bowels will bear forced feeding and what food will be best taken, digested and absorbed. With these points determined, he maps out a diet list containing from 2,200 to 2,500 calories, and gradually increases this to from 3,800 to 4,500 calories. This extreme diet is divided by him into 250 grains of fat, 150 of albumin and 400 of carbohydrates, amounting altogether to 4,580 calories. He also gives tonics and pushes them to the physiological limits if necessary. In nervous individuals he uses nerve sedatives, but never narcotics. From time to time he notices the excretory activity of the kidneys and compares it with the water intake, which should be from 2,000 to 3,000 c.c. Exercise is lessened or increased according to the demands of the case, and Breisacher also uses tepid baths, cold rubs, massage and electricity. Under this treatment patients often gain very rapidly

in weight, calling sometimes for reduction in diet. The chronic underfed usually require from two to six months' careful treatment of this kind.

The Fetich of Disinfection.—The value of modern disinfection methods, as applied after cases of contagious disease, is questioned by C. V. Chapin, who, while not denying the possibility, thinks that cases of transference of disease by infected articles and dwellings are very rarely well authenticated. In his experience of twenty-two years as health officer he has seen very few of them, and has become convinced of their comparative unimportance. We are apt, he thinks, to overestimate the vitality of germs outside of the body and to underestimate the importance of mild, unrecognized cases of infectious diseases as factors in its spread. Healthy individuals are also carriers of disease germs, and as such are more numerous than the mild unrecognized cases of the disease itself. A good deal of disinfection, moreover, does not disinfect, and the futility of disinfecting houses and things when we are not sure that the persons inhabiting them or using them are themselves noninfectious is obvious. A practical test of the nonutility of disinfection has been made in Providence. During the past year the warning card has been removed without disinfection in 258 cases of diphtheria, and there has been a recurrence in the family within two months in four cases, or 1.55 per cent. In eighty-seven cases in which disinfection was practised during the same period, or a few months preceding, there was a recurrence in 2.3 per cent. of the cases. The overestimation of the value of disinfection is, he thinks, the greatest hindrance to the development of better methods of handling disease and guarding against infection.

Studies on Phagocytosis.—D. H. Bergey relates briefly some experiments made to ascertain whether the opsonic power of blood serum was efficacious against certain classes of microorganisms, and also to determine whether or not the macrophages of Metchnikoff participated in the phagocytosis. His experiments were carried out with the peritoneal exudates of guinea-pigs following aleuronat injections. The exudate was mixed with equal quantities of 0.85 per cent. sodium chloride and then added to the various bacterial suspensions in equal proportions in capillary tubes. These tubes were incubated at from 34 to 36 C. for thirty minutes, when smears were prepared which contained as nearly as possible equal numbers of bacteria, but no attempt was made to have an equal number of bacteria for the several tests, so that the different exudates did not contain equal numbers of bacteria. A series of ten experiments was carried on with the exudate obtained from ten different animals by employing the following cultures: *Bacterium pseudodiphtheriticum;* two cultures of *Streptococcus pyogenes*, one from urine and from the throat in a case of scarlet fever; *Micrococcus catarrhalis; Micrococcus pyogenes albus* and *Micrococcus aureus.* The results are shown in tables. A series of five experiments was undertaken with the view of ascertaining the range of bacteria susceptible to phagocytosis under similar conditions. For these observations, the following organisms were used: *Micrococcus aureus, Microspira schuylkillensis,* and *Bacillus dysenteriæ* Shiga. The results obtained in this series of observations are also shown in tables. These results are too few in number and too erratic, Bergey states, to warrant the formulation of any definate deductions. In several instances no phagocytic action could be demonstrated, and doubt existed usually as to whether the spirilla and dysentery bacilli were really within the phagocytes or were merely lying on them, or adherent to their exterior. The results indicate that the opsonic power of the blood serum is much more pronounced for those bacteria which induce septicemia than for those in which a more distinct bactericidal immunity is induced.

The Lancet, August 11, 1906.

Amblyopia in Young Children Consequent Upon Inherited Syphilis.—Sydney Stephenson called attention to a condition which obviously represents a secondary manifestation of congenital syphilis, and which corresponds with the retinitis, choroiditis, or retinochoroiditis sometimes observed in the acquired form. In both the congenital and acquired forms it is unusual for one eye to be alone affected. He makes the point about infantile amblyopia that in babies "hyalitis" forms the leading ophthalmoscopic feature, while the underlying choroiditic or retinitic lesions may be relatively insignificant or altogether hidden by the cloudy vitreous humor. In his opinion, in babies, a cloudy vitreous humor means the existence of congenital syphilis. He reports six cases, in four of which the hazy vitreous cleared up under the influence of mercury. In none of his cases of infantile amblyopia were there any evidences of iritis.

A Successful Case of Splenectomy for Rupture of the Spleen.—Graham S. Simpson reports the case of a man, 27 years old, who fell a distance of twenty feet. Four hours afterwards he complained of severe pain in the abdomen, was pale and looked anxious, with breathing jerky and thoracic, pulse 140, temperature 100° F., and respirations 50. The abdomen was rigid and did not move with respiration. Liver dullness was present and there was some dullness in the epigastrium. At operation a large transverse tear, starting from the hilum and nearly separating the lower third of the organ was found. A long pair of artery forceps applied to the pedicle stopped the hemorrhage, making the rest of the operation a simple one. The spleen was brought round, in front of the stomach, the pedicle was transfixed and ligatured, the spleen was excised and the wound sewn up in layers. A slow recovery followed.

British Medical Journal, August 11, 1906.

The Microscopic Changes in the Nervous System in a Case of Chronic Dourine.—F. W. Mott says that dourine, or "mal de coit," is due to a specific form of trypanosome which has the power of penetrating the mucous membrane, affects equines, and is transmitted by coitus, of special interest since the demonstration of the *Spirochæta pallida* of syphilis. A comparative examination of the nervous tissue of this disease with those of animals infected with *Trypanosoma gambiense,* and with the tissues of human beings dying of sleeping sickness appears to show that chronic trypanosome infection causes a chronic lymphadenitis, followed later by an interstitial inflammation of the connective tissue structures of the nervous system.

Antistreptococcus Serum in Empyema.—John Wm. Ingles reports the case of a boy, 11 years old, suffering from an acute pleurisy with effusion on the left side. He was strumous. Eight days after he first saw the child, pus was found and operation refused. Antistreptococcus serum, in 10 c.c. doses, was administered which was followed by an adventitious rash and aching throughout the body, which soon disappeared. Two weeks after the first administration of the serum the child was out of bed and the cough had entirely disappeared. A rapid return to health followed.

Berliner klinische Wochenschrift, August 6, 1906.

Myeloid Degeneration.—Hirschfeld submits some further studies on myeloid metaplasia, as an addition to his earlier observations. In three cases of lymphatic leukemia he was able to demonstrate myeloid degeneration in the spleen as well as in the lymphatic glands. This shows that there is no sharp line of distinction between lymphocytes and granulocytes as hitherto assumed, and that likewise there is no difference in reality between lymphatic and myelogenous leukemia. Although these diseases may be separated from the standpoint of etiology and histology, the cases reported by the writer show that there are transition stages between the two.

Head's Zones in Diseases of the Digestive Organs.—Kast, in an extended discussion of this subject, claims that the phenomenon in question cannot be explained by the mere extension of a pathological process in the internal organs secondarily involving the cutaneous nerves. It is well known that the various parts of the digestive tract are practically insensitive to the ordinary stimuli. Such a condition would really be superfluous, as these viscera do not under normal circumstances, receive stimuli of this character. The stomach, intestines, ureter, heart, etc., all receive their stimulus from within, and it is from this direction that the cause of any aberration of function must be sought. Kast finds that in certain diseases the zones are by no means constant; thus out of twelve cases of undoubted carcinoma of the stomach, the sign was only elicited in one, and in this instance the process had been transmitted from the esophagus. Then on the other hand the zones may be present with a great variety of conditions, such as gastritis, neuroses, achylia, or ulcer, so that no definite conclusions are possible as to the exact diagnosis of the complaint.

Münchener medicinische Wochenschrift, August 7, 1906.

Acute Dilatation of the Stomach.—Neck calls attention to the necessity of making an early diagnosis of this condition, which unless recognized in time may lead to very serious results. The four cases which he reports serve as a basis for a brief discussion of the

subject and its treatment. The symptoms are marked by the appearance of sudden and severe vomiting, accompanied by more or less pain in various parts of the distended abdomen. The pulse is small and rapid, but there is no rise of temperature. The absence of the latter is important, because by this sign the condition may be differentiated from a peritonitis. Another sign of value is the presence of evidences of a localized collection of fluid on the left side of the abdomen. Neck finds that among sixty reported cases, a correct diagnosis was made in only thirteen instances, and this usually by men who had previously treated the condition without having recognized the true state of affairs until an autopsy was made. Neck thinks that the diagnosis can best be confirmed by the introduction of the stomach tube. The prognosis, unless correct treatment is instituted at once, is bad. The mortality in the sixty-four cases which have been published, is 47. The first point in treatment is to favor the evacuation of the stomach, which is best accomplished by placing the patient in an elevated pelvic position. During the first few days, gastric lavage should be regularly done, and no food is to be given by mouth until the stomach has recovered its tone. The necessary fluids may be provided by the administration of normal salt solution subcutaneously or by rectum. Nutrient enemata are also indicated and the heart must be properly stimulated. This form of gastric dilatation is also apt to be complicated by disturbances in the duodenum marked by distention of this organ brought about by the tension on the mesentery. This may also involve other portions of the gut, and will be relieved by the treatment directed towards the gastric condition. If this is ineffective, then a laparotomy is indicated.

Behavior of the Typhoid Bacilli in the Blood.—Lemierre discusses this phenomenon in relation to the bactericidal action of the blood. He made a series of experiments in order to determine how long the defibrinated blood of typhoid patients could be kept in the undiluted form without the contained typhoid bacilli being killed off. It seems that there is a period during which the growth of the bacilli is inhibited, but after this the resistance is overcome and the bacilli proliferate very quickly. The practical use to be made of this observation is that blood from typhoid patients may be kept for several days in the defibrinated state, before it is diluted with the nutrient medium.

A Simple Apparatus for the Bier Treatment.—Muck describes a substitute for the rubber suction bulb which he has used with good results in treating tubercular otitis media and other conditions. The rubber bulb in this contrivance is replaced by a glass ball in which the vacuum is produced by the aid of an ordinary suction syringe. The neck of the glass bulb is connected with a rubber tube, which is provided with a clamp, and after the air is exhausted, this is attached to the cup. On releasing the clamp the air from the latter finds its way into the glass bulb. The entire apparatus may be readily sterilized, and can be constructed very cheaply.

Deutsche medizinische Wochenschrift, August 9, 1906.

Unusual Complications of Typhoid Fever.—Pfister thinks that the irregular course of this disease and its attendant complications are due most likely to some inherent differences in the bacilli themselves, although thus far we have been unable to distinguish them by any known laboratory methods. In one of the cases reported there developed during the second week of an unusually mild attack of typhoid fever, a pneumonic process in the left lung. Although the typhoid subsided, the pulmonary process persisted unchanged, with continued irregular temperature. On the forty-third day of the disease, the patient suddenly coughed up about a pint of pure pus, and then the pulmonary signs and the temperature subsided for a time, only to be renewed until another collection of pus was coughed up. Then the patient made an uninterrupted recovery. In the second case a membranous enteritis appeared during the period of convalescence. The writer thinks that the typhoid process served in this instance to bring on the secondary enteritis, due to the irritation of the diarrheal discharges combined with a specific toxic action. In the third case a rapidly increasing coma appeared on the seventh day of the disease. The patient died in this state and a meningeal involvement was suspected. The autopsy showed extensive meningeal hemorrhages, which, together with the bleeding into a number of other organs, seemed sufficient to account for the profound anemia observed during the last few days of life. Such hemorrhages during the course of typhoid fever are quite rare and there is nothing certain in regard to their etiology. Probably they are analogous to the hemorrhages observed during the course of a severe sepsis.

Is Appendicitis More Frequent in Men or in Women?—Karrenstein has collected the figures from some of the larger German institutions, from which it appears that the sexes are about equally affected. During one year, however, there was a marked preponderance of cases among women. In looking up the statistics of acute intestinal catarrhs, influenza, and tonsillar inflammations, conditions which are believed to have an important bearing on the etiology of appendicitis, it was found that with the exception of the year noted, the female sex was less frequently afflicted than the male. These figures refer to institutions in Berlin, but in those of Hamburg, which were similarly studied, it was found that women were more often the subject of appendicitis than men. But here likewise it was found that the other disturbances just referred to were also more prevalent in the female sex. These figures seem to show that the male sex cannot claim a monopoly in this disease.

The Use of Alkalized Buttermilk as Infant Food.—Moll in a previous article announced the result of his experiments with this preparation, which can, it seems, be given with advantage either alone or as an addition to breast feeding, particularly in chronic gastrointestinal complaints. Among the objections urged against the method was the fact that this preparation could not be given for any great length of time without producing further disturbances. Moll now advises that the milk be given at first in more dilute form so that the infant will become more gradually accustomed to the new diet. He has used it in a large number of cases and the milk may be readily prepared at home by the addition of the prescribed alkaline powder to ordinary buttermilk. This powder consists of milk sugar and cane sugar, each 20 grams, rice flour, 9 grams, and dry sodium carbonate, 3 grams; this quantity is sufficient for one liter of milk.

The American Journal of the Medical Sciences, July, 1906.

Further Observations on the Anatomy of the Duodenum.—A. J. Ochsner some time ago directed attention to an anatomical condition of the duodenum, consisting in a marked thickening of the circular muscle fibers at a point below the entrance of the common duct. He proved this by a large number of dissections. The position of these muscle fibers varied. In some cases they formed a narrow circular band; in other cases the thickening was diffused; in still a few more there were two different bands. There was a difference in the location of this duodenal sphincter, though as a rule it was situated from three to ten c.c. below the point of entrance of the common duct. The writer believes that these conditions explain a number of physiological facts: the fact that vomiting when the stomach is comparatively empty always expels a certain amount of bile; and the fact that in many cases, in which there is a dilatation of the stomach without constriction of the pylorus, with an ulcer in the pyloric end, the ulcer often extends into the duodenum. It may explain some of the gastric symptoms observed in gallstone disease. It also explains the presence of a greatly distended duodenum with a completely contracted first part of the jejunum often noted in operations for the relief of gallstones and ulcer of the stomach. Further it explains the presence of the bile-staining of the duodenum above the comman duct in the cadaver. The writer also suggests that this arrangement of circular muscle fibers may serve the purpose of a sphincter to facilitate the process of mixing the bile and the pancreatic juice in the duodenum.

The Sufficiency of Simple Intercostal Incision in Acute Empyema, with a Report of Five Cases.—James Farquharson Leys believes that simple intercostal incision is the best treatment for acute empyema. The operation is performed through an intercostal space. Resection of a rib is not only quite unnecessary, but practically undesirable in all cases of acute empyema. The writer reports the history of five cases, describing the operation as follows: Local anesthesia is produced by a lump of ice dipped in coarse salt and held against the chest, or with a spray of ether from a hand atomizer, or with a spray of ethyl chloride. The patient is propped into a sitting posture. The implements used are a scalpel, a pair of blunt straight scissors, two pairs of hemostatic forceps, about twelve inches of three-eighths inch rubber drainage tubing, fenestrated on alternate sides at intervals of an inch, and four large safety pins at least two inches long. All of these articles as well as the dressings and the patient's skin are carefully sterilized before the operation.

The Advisability of Eliminating the Terms Ménière's Disease and Ménière's Symptoms from Otological Nomenclature.—Emil Amberg, after discussing this subject, concludes that the triad—hardness of hearing, vertigo, and tinnitus, is given as constituting the functional disturbance observed in the so-called Ménière's disease. These symptoms occur also in numerous affections, which are not based on the pathological finding as described by Ménière in his historical case. The observation that not always a typical picture is present, has led to the introduction of other terms, such as "Ménière's symptoms," etc., which have proved to be confusing. Even affections of the middle ear, of the outer ear, or of other parts of the body can cause the symptoms described by Ménière. These latter causes can be diagnosed in many instances, and prove the existence of a great group of affections characterized by functional disturbances of the inner ear. By abandoning the terms "Ménière's disease" and "Ménière's symptoms" a more definite nomenclature can be introduced. This is important, not only from a physiological and pathological, but also from a clinical standpoint. By using, for instance, the terms "otitis interna syphilitica," or "leukemica," or "angioneurotica," or "gastrica," a clearer conception of some affections would ensue. The various terms should be agreed upon. The many international medical meetings give ample opportunity for such an agreement.

Alcoholic Multiple Neuritis.—Charles W. Burr declares that multiple neuritis is as a rule easily diagnosed. It is never difficult to differentiate it from cerebral palsy, but it is sometimes almost impossible to determine whether or not there is also disease of the spinal cord. In children the question may arise whether acute anterior poliomyelitis or neuritis is present. In the former there is never muscle pain, nerve tenderness, nor areas of skin anesthesia. The determination of the cause of the disease is far more difficult than the recognition of its seat. There are two distinct types of this affection, the one chronic, the other distinctly acute. Many of the acute cases are engrafted upon the chronic disease. More laboring men suffer than any other class. The prognosis in multiple neuritis without serious mental symptoms is good, as a rule. In some cases recovery is complete. The writer cites the histories of a number of cases.

Experiments on the Great Omentum.—Leonard S. Dudgeon and Athole Ross state that it is an undoubted fact that the great omentum plays a very important part in the bacteriology of peritonitis, but of still greater importance is its relation to cellular pathology. Their experiments lead them to believe that the *Staphylococcus albus* is often present as a normal inhabitant of the omentum; and that when non-bacteriological substances are injected into the peritoneal cavity of animals the *Staphylococcus albus* can usually be recovered from the great omentum. By one of these investigators there has been cultivated the same white coccus from the omentum in many cases in which the peritoneum was opened, apart from peritonitis. In all these cases the pieces of omentum were dropped into culture tubes of broth, and the growth investigated in the usual way.

The Practical Significance of a Trace of Albumin in the Urine.—Joseph P. Tunis presents these conclusions: 1. From any point of view the term "physiological albuminuria" is almost universally regarded as misleading, unsatisfactory, and inadequate. 2. As long as albumin is a constituent of the urine the individual voiding it cannot be regarded as normal. 3. The mortality among such persons must necessarily be higher than among an equal number of individuals who do not show this phenomenon. 4. The actual mortality rate among this class can best be approximated by a comparison of the records of half a dozen of the largest life insurance companies (dealing with hundreds of thousands of cases) over a period of twenty years at the least. 5. The prompt means of discriminating between the transient forms of albuminuria and those of real clinical significance may be found in some such therapeutic test as that of calcium lactate, rather than by any further developments in the chemistry of the urine. 6. Experience proves that a faint trace of albumin in the urine of an individual past middle life is often of greater significance than a decided trace by unexpectedly directing attention to the finding of casts of pathological importance, which might otherwise have been easily overlooked. 7. For practical purposes the heat and nitric acid test for albumin is the best one, and the careful use of Roberts' solution the most satisfactory control test in doubtful cases. 8. For the proper diagnosis and prognosis too much stress cannot be laid on a thorough consideratin of the clinical conditions as a whole.

French and Italian Journals.

Primary Malignant Tumors of Bartholin's Gland.—In a recent thesis by G. Chaboux, the author reports, besides one personal case, eleven observations of this nature. The histological examinations of seven of these which have been collected from the literature are given. The writer, in collaboration with M. A. Gambou, has made a series of researches on the histological structure of the normal gland. They demonstrate that the vulvovaginal gland is not formed of glandular bodies disseminated throughout the tissues of the labia majora. Its structure is homogeneous, and it is surrounded by a connective tissue capsule. The gland is not striated with muscular fibers. There are only a few smooth fibers around the large ducts. Chaboux finally describes the different clinical forms of the malignant primary tumor. They are quite rare, and are often consecutive to bartholinitis. The progress as a rule is rapid. The recurrences in the inguinal ganglia are frequent. Early and extensive ablation is indicated as well as thorough curettage of the inguinal region.—*La Presse Médicale*, June 20, 1906.

Puerperal Anuria. Decapsulation of the Kidney. Death.—Henri Hartmann reports this case. The patient, a woman twenty-seven years old, gave birth to her first child at the age of twenty-one. Normal delivery at this time was followed by eclampsia and an albuminuria, which disappeared at the end of a few months. There was a premature birth three years later, and again in two years, a second delivery at term without incident. On March 6, 1905, the patient was normally delivered at term. Nothing of importance was noted. Diarrhea had been present during the eight days that had preceded the birth. Forty-eight hours later the temperature rose. During the entire day the patient could not void a drop of urine. The anuria persisted for the following days. It was accompanied by vomiting and by bilious glairy stools, which were slightly bloody. On March 18 the general condition was grave, and the patient was in a semi-comatose state. Examination of the abdomen and uterus showed nothing of interest. With the cathether twenty cubic centimeters of turbid urine, slightly colored by blood, were withdrawn. The specific gravity was 1.013; there were no casts, but leucocytes and red blood cells were present. On the next day decapsulation of the right kidney was performed. On March 21 the patient died. At operation the kidney was found to be turgid. This organ had been under great compression, and its condition indicated decapsulation, in spite of the failure of intervention.—*Annales de Gynécologie et d'Obstétrique*, June, 1906.

Coexistence of Two Cancers of Different Nature in the Same Individual.—Aynaud describes these growths. The patient was a man sixty years old. About four months before he came to the hospital he noticed a small nodule near the frenum of the tongue, a little to the left. It grew to the size of a nut; it was adherent and its surface was bosselated. The entire region was infiltrated. The patient had also suffered for three months with gastric pains, which were vague, and not clearly localized. For two months he had vomited daily, and his cachexia was very pronounced. At autopsy the two neoplasms were found to be independent of each other. The buccal growth proved to be a cancer of the lingual mucosa. The tumor was a typical epithelioma of the pavement cell variety. The pyloric tumor was of the cylindrical type.—*Bulletins et Mémoires de la Société Anatomique de Paris*, February, 1906.

Effect of Injections of Saline Solution and Distilled Water in Nephrectomized Animals.—A. Campani found that nephrectomized animals into whom was injected distilled water lived much longer than those untreated. Saline solution did not have this effect in prolonging life. After the use of saline solution the blood in the heart was liquid, while after distilled water it coagulated normally. It made no difference whether the injections were hypodermic or endovenous as to the effects obtained. The author cannot as yet give any reason for the beneficial effects of distilled water, but puts forward the hypothesis that the migrating of the motor among the tissues, so as to keep up a normal amount of blood concentration, retains many of the organic waste materials and prevents them from entering the blood and poisoning the system. Saline solution cannot be used in sufficient concentration to have this beneficial effects.—*La Riforma Medica*, June 16, 1906.

Book Reviews.

THE PHYSICAL EXAMINATION OF INFANTS AND YOUNG CHILDREN. By THERON WENDELL KILMER, M.D., Adjunct Attending Pediatrist to the Sydenham Hospital; Instructor in Pediatrics in the New York Polyclinic Medical School and Hospital, New York. Philadelphia: F. A. Davis Company, 1906.

THE author was led to write the present little volume by the "deplorable ignorance of most physicians as to the methods of examination of babies." Accordingly the book is a primer of the subject, written from the viewpoint of the teacher of a spelling class, and will be found useful by those who for the first time do clinical work among infants and children. In addition to the methods of general diagnosis, the book treats very briefly of the examination of the throat, nose, ears, eyes, blood, stomach contents, breast milk, and the collection of urine and sputum. The method of lumbar puncture is also outlined. The illustrations for the most part show what they are intended to show and the book will surely be found satisfactory by those who seek to know the rudiments of the examination of little children.

THE PRACTICAL MEDICINE SERIES. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Volume I: General Medicine. Edited by FRANK BILLINGS, M.S., M.D., Head of Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. SALISBURY, A.M., M.D., Professor of Medicine, Chicago Clinical School. Volume II: General Surgery. Edited by JOHN B. MURPHY, A.M., M.D., LL.D., Professor of Surgery in Rush Medical College, Chicago: The Year Book Publishers, 1906.

THE year 1905 did not bring anything very startling in the field of general medicine. In all branches of this field however advances have been made, especially in diagnosis and treatment, and in the collection of data on etiology. As might be expected, tuberculosis led the way, with typhoid fever, rheumatism, cerebrospinal meningitis, etc., following closely. To the physician who has not the time or the inclination to read every important journal the present volume will offer an easy road to a sufficiently detailed comprehension of all the progress that has been made in our knowledge of the principal internal diseases. In the second volume we have in the space of 583 duodecimo pages the record of the year's progress in surgery from anesthesia to *x*-rays. Of course, not every topic has been considered with equal fullness, but a praiseworthy attempt has been made to treat most exhaustively those subjects which appeal to the practical man. As may be expected in a book edited by Murphy, the chapter on intestinal surgery is most complete, and reads with sustained interest.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures, and Especially Prepared Original Articles. By Leading Members of the Medical Profession Throughout the World. Edited by A. O. J. KELLY, A.M., M.D., Philadelphia, U. S. A. Volume I, Sixteenth Series, 1906. Philadelphia and London: J. B. Lippincott Company, 1906.

THE present volume does not differ essentially from those of the preceding series. Twenty-one original articles are included in its contents. Of these eight come from Philadelphia, New York is represented by two, Chicago by three, Boston by two, and Baltimore by two, while one comes from California. Foreign countries are represented by two articles from Paris, one from London, and one from Berlin. The character of these contributions is excellent. In the reviewer's opinion it is a mistake to combine the potpourri of medical progress with the "International Clinics." The latter could well afford to stand alone, while the review of medical advances demands separate and far more complete treatment to be of any real value.

DIE BASEDOW'SCHE KRANKHEIT. Von Dr. P. J. MÖBIUS in Leipzig. Second Revised Edition. Vienna: Alfred Hölder, 1906.

MÖBIUS has for ten years past contributed the reviews on the subject of Exophthalmic goitre to Schmidt's Jahrbücher. To anyone who is familiar with this venerable retrospect of medicine this at once conveys the thought that the author must have read and reviewed every article of importance on the subject. There were over 400 such articles published in the last ten years, and the present volume is a systematic account of Basedow's disease in the light of this literary material. Beginning with a brief historical note, the etiology, as we know it, of the disease is considered; the various symptoms are then described in turn, the complications, the clinical forms, the diagnosis and prognosis each receive their quota of attention, while the chapter on treatment completes the book. Very few German medical authors can be named who can surpass Möbius in lucidity of style, in unity and balance of exposition, and in the living interest of their pages.

GEISTESKRANKHEIT UND NATURWISSENSCHAFT; Geisteskrankheit und Sitte; Geisteskrankheit und Genialität, Geisteskrankheit und Schicksal. Von Dr. Med. HEINRICH STADELMANN, Nervenarzt in Dresden. Munich: Otto Gmelin, 1905.

IN these four little essays, which are mere outline sketches, the author attempts to present the relation of insanity to natural science, to custom, to genius, and to fate. Rather a large undertaking, but he pleads his cause well in the limited space he occupies.

THE COMBINED TREATMENT IN DISEASES OF THE EYE. By G. HERBERT BURNHAM, M.D.Tor.,F.R.C.S.Edin., M.R.C.S. Eng., Professor of Ophthalmology and Otology at the University of Toronto; Original Member of the Ophthalmological Society of the United Kingdom; Oculist and Aurist to the Mercer Eye and Ear Infirmary, and General Hospital, Toronto, Canada. London: H. K. Lewis, 1906.

THE work is a monograph of 92 pages devoted to a consideration of the value of mercury and the iodide of potassium in combination with pilocarpine in the treatment of certain diseases of the eye. The method of the use of these drugs as advocated by the writer is minutely described. He terms this form of treatment "The Combined Treatment." Chapter I contains the theory of the action of the remedies, the manner in which they should be given, and general remarks. Chapters II to VIII, inclusive, are devoted to the reports of cases. Chapter IX is a general summing up of the whole subject. The subject as put forth by the writer is worthy of consideration by ophthalmologists, as it discloses a careful study of the effect of the remedies in many obstinate diseases of the eye.

ENIGMAS OF PSYCHICAL RESEARCH. By JAMES H. HYSLOP, Ph.D., LL.D., formerly Professor of Ethics and Logic in Columbia University. Author of "Science and a Future Life," etc. Boston: Herbert B. Turner & Co., 1906.

THIS volume is intended as a supplement to the author's previous book on "Science and a Future Life." The eleven chapters of which the work consists are supposed to cover the whole field of the supernormal, and deal with the residues of science, the ancient oracles, crystal vision, crystal gazing, telepathy, dreams, apparitions, clairvoyance, premonitions, mediumistic phenomena, retrospect, and vaticination. Most of the selected illustrations are old and are said to have received the *imprimatur* of the Society for Psychical Research. What the exact value of this may be, we do not presume to say; but it is very certain that in most cases we have only the *ipse dixit* of the dreamer or crystal gazer. The author says that "the passionate interest of men is turning either to science or to illusion and folly for guidance." We have no hesitation in recommending science as by far the better of these alternatives; but while the present volume is interesting in a way, what science there may be in it is so deeply buried that we have failed to find it.

TRANSACTIONS OF THE NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY AND THE CARE AND TREATMENT OF EPILEPTICS; Volumes II and III: 1902 to 1905, inclusive. Edited by WILLIAM P. SPRATLING, M.D.

THIS works contains the transactions of the annual meetings of the foregoing Association from 1902 to 1905 inclusive and appears in two volumes, II and III; volume I having been published in 1901. Volume II contains the Presidential Address of Dr. Frederick Peterson in 1902 and that of Dr. Wharton Sinkler in 1903. It also contains 21 scientific papers that bring concisely under review all phases of epilepsy, including its etiology, diagnosis, pathology; clinical manifestations, and treatment; as well as reports on the public care of epileptics. Volume III contains the Presidential Address by Dr. William N. Bullard, for 1904, and that of Dr. William P. Spratling, for 1905. In the main this volume is given over to scientific papers on epilepsy; though it has a section made up of reports from many foreign countries and from all of the States in this country in which public provision for epileptics has been made. On the whole the facts presented in these transactions are peculiarly valuable and comprehensive and probably cannot be duplicated or exceeded by any other collection of papers of like purport on this extraordinary disease.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-ninth Annual Meeting, Held at Bristol, August 21, 22, 23, 24, and 25, 1900.

Special Report to the Medical Press.

(Continued from page 310.)

GENERAL SESSIONS.

Second Day—Wednesday, August 22.

Address in Medicine.—Sir James Barr of Liverpool, who delivered the address in the afternoon session, chose as his subject, "The Circulation Viewed from the Periphery." He said that diseases of the heart most frequently arose from causes acting on the periphery, and the man who studied the circulation with the stethoscope was a positive danger to society. The capillaries constituted a vast filter bed for conveying nutritive material and oxygen to the tissues, and for removing waste products therefrom. Velocity and pressure were studied; they might be said to stand, within certain limits, in an inverse ratio to one another, the more rapid the flow the less the lateral pressure, and vice versa. The lateral pressure depended on the statical condition of the blood, and just in proportion as one introduced movement one converted the force of pressure into that of velocity. He had recorded capillary pressures varying from 50 to 2,000 mm. of water, and velocity records have ranged from about 0.5 mm. to over 25 mm. per second. The viscosity of the blood varied greatly and was no doubt the great cause of resistance in the capillaries. Normally it was about five times that of distilled water. In many diseases it was nine or ten times that. Viscosity was an important element in the resistance; it was increased by CO_2 and diminished by heat; it was also increased by salts of calcium, magnesium, and strontium, and diminished by decalcifying agents. He then considered the interchange of material through the capillary walls. The so-called digestion leucocytosis was no evidence of increase of white cells in the circulating blood, but merely that lympth had been passed out from the vessels, and in this lympth there was a considerable number of lymphocytes, probably obtained from the tissues rather than from the capillaries. There was no doubt a digestion leucocytosis, but it was not what had been described. The arterioles and capillaries of the splanchnic area were well supplied with vasomotor nerves, which were the chief regulators of the arterial blood pressure. The resistance to the outflow was very slight, except in cases of portal obstruction; hence the velocity was usually great and the lateral pressure slight. The velocity in the capillaries of the liver was often so slow that the liver was of a dull purple color and the pressure was relatively but not absolutely high. The liver acted as a reservoir for the right side of the heart. The vasomotor nerves supplying the arterioles and capillaries of the kidneys protected the capillaries of the glomeruli from any excessive pressure; thus high arterial pressure increased the velocity in the glomeruli, but not necessarily the lateral pressure. The glomeruli were further protected by Bowman's capsule, and again from any backward venous pressure by a second set of capillaries into which the efferent vessels divided. With lessened velocity and lowered pressure the concentration of the filtrate was increased. In granular kidneys the glomeruli were further protected by an increased thickness of Bowman's capsule; the velocity was much increased and the pressure only relatively so; the filtrate was bulky, but not concentrated. There was nocturnal diuresis because of the horizontal posture. The spleen appeared to have the power of contracting and regulating its own blood supply, and adrenalin had a powerful effect in producing contraction. The cerebral vessels were not very contractile, and took no part in regulating the general arterial pressure. Owing to the stress and strain to which they were frequently subjected they were liable to atheromatous and calcareous degenerations of the internal coat, and thickening of the external coat; there were also frequently seen small miliary aneurysms. The velocity was enormously increased at times, but not the lateral pressure. The arterioles which supplied the heart resembled the cerebral vessels in being thin-walled and having very few vasomotor nerves, if any. When the coronary artery was blocked the heart might be supplied with blood from the venous side. The pressure in the pulmonary artery was not more than one-third, and the velocity of the blood about three-fourths of those respective conditions in the aorta; but the pressure in the pulmonary veins was always positive, so that the blood always entered the left side of the heart under pressure, while it was usually sucked into the right side. There was a gradual fall of the pressure-gradient from the right ventricle to the left auricle. The lungs formed a blood reservoir for the left side of the heart. The pressure in the capillaries was usually higher than that in the veins because their sectional area was greater and there was greater friction, but if the arterioles were much contracted, a tenth or even a twentieth of the capillaries might not be filled with blood, and the sectional area might fall even below that of the vessels collecting the blood. The veins and arteries then received his attention. The former have very flaccid walls and readily adjusted their cubic space to the amount of blood in transit. The lateral pressure in the systemic veins depended on the obstruction to the inflow to the chest, the hydrostatic effect of the column of blood, and the potential energy transmitted through the capillaries. In the portal vein the pressure was always positive, and in this respect it resembled an artery. Certain observations showed how kinetic and potential energy in every part of the circulation was constantly varying. The blood in the veins was one of the very few things which ran more quickly up the hill than it did down it. After describing the constitution of the arteries he said they were well supplied with nutritive vessels and richly endowed with vasomotor nerves. As the blood left the heart it was largely kinetic. The velocity of the blood in the aorta and pulmonary artery varied, and was directly as the cardiac energy and inversely as the resistance to the outflow and the sectional area. The velocity in the pulmonary artery was nearly equal that of the aorta. A clear comprehension of velocity and pressure in the aorta he believed of great importance in explaining the cause of death in people after the age of 50 years from arteriosclerosis. The most perfect circulation was one with a small difference between the systolic and the diastolic pressure; this difference could be looked upon as that part of the energy which was not stored up in the walls of the arteries and which was engaged in producing velocity. When this difference exceeded 40 mm. of mercury there was something wrong with the elasticity of the aorta and the damage should be repaired. With a continuous lateral pressure of 200 mm. of mercury or more there was no period of repose for the vessels, but merely periods of greater or less distention; there was interference with the circulation in the nutritive vessels, and one got irritative and proliferative changes in the subendothelial layer of the intima if atheromatous and perhaps calcareous degeneration followed, and the elasticity of the aorta became impaired. In proportion to the loss of elasticity the energy of the heart was not stored up, and with the loss in the conservation of energy the heart had

more work to do, and a great disparity arose between the systolic and diastolic pressures. The immediate resistance to the outflow from the heart was not increased, but the total work was greater, the diastolic pressure in the heart arose, and the ventricle dilated and hypertrophied. The output was increased, the velocity was increased, and longitudinal straining occurred. One might now get a difference between the diastolic and systolic pressures of 120 to 130 mm. or more of mercury, then there would be a marked recoil of the heart at the end of the systole, and negative and positive waves in the circulation would obstruct one another. Here storage was defective and the velocity more or less intermittent, and there was an enormous waste of energy. The question of storage formed an important element in prognosis and for this reason aortic regurgitation occurring early in life from a rheumatic lesion was, *cæteris paribus*, very much less serious than a similar lesion arising secondary to degeneration of the aorta. If there was any elasticity left in the aorta and principal branches, there was an advantage in aortic regurgitation in maintaining a relatively high diastolic pressure and well regulated doses of digitalis and squill often did an enormous amount of good. While they increased the peripheral resistance they lessened the size of the ventricle, increased the length and completeness of contractions, diminished the residual blood, and thus lowered diastolic pressure in the ventricles. A brief consideration of arterial blood pressure and the heart concluded the address.

Address in Surgery.—Sir Victor Horsley of London, delivered this address at the evening session, taking as his title "The Technique of Operations on the Central Nervous System." In reviewing the technique and procedure of encephalic operations he considered the essential steps of such operations *seriatim*. The general preparation of the patient was the same as in all operations, and in some instances he found calcium chloride of probable service in cases where oozing of blood from bone or superficial tissues was to be expected. The head and cavities in relation to it should be thoroughly disinfected for two or more days, and the patient placed on the table in such a way that, while the head was elevated to diminish pressure in the venous sinuses, the shoulders were also slightly elevated, so that glottic respiration should not be interfered with. His own experience was confined to general anesthesia. Ether he regarded as inadmissible as an anesthetic in operations on the central nervous system. Chloroform was used and its dose regulated. To maintain the physiological energy of the central nervous system and prevent shock it was necessary to prevent cooling by radiation from the brain exposed in the wound; the wound, therefore, should be constantly irrigated. This tended to arrest capillary and arterial hemorrhage, as well. To control hemorrhage the tying of the carotid should be avoided. He advocated tying all the arteries around the lesion before extirpating it. It was remarkably easy to control capillary oozing and arterial oozing from the brain by the simple means of hot irrigation. The bleeding from the veins and sinuses in bone could be certainly arrested by plugging with wax if the periosteum round the hole was completely removed. Venous bleeding commonly occurring in association with capillary oozing could be controlled by the inhalation of oxygen. One should discriminate between collapse and shock. The former was a temporary accident, in which the patient's nerve centers were capable of being revived by ordinary clinical means; shock was a post-operative condition, which deepened after the operation for a variable period, and which, if it terminated fatally, destroyed life, as a rule, within twenty-four hours. The majority of deaths occurred from a severe degree of shock that could be in part avoided by dividing the operation into two stages, the interval between them being about five days. The first stage consisted of the opening of the skull; the second of opening the dura mater and removal of the lesion. It was the opening of the skull which caused most general depression of nerve energy and most alteration in the circulation. He next considered the method of opening the skull and believed that the bone should be divided with as little vertically applied force as possible, and removed with the least possible pressure on the brain and dura beneath. In speaking of the influence of the region of the skull opened he gave the following: "Motor area," the proportional ratio was 1 death in 27 operations; parietal and post-parietal regions, 1 in 19; frontal region, 1 in 13; temporal region, 1 in 12; cerebellar region, 1 in 10. Therefore it was obvious that more shock resulted from operations below a line drawn from the frontal eminence to the occipital protuberance. The readiness with which the cerebrum and cerebellum became edematous was remarkable, and it was generally believed that this occurred whenever the skull was opened. Its occurrence was clearly associated with unrelieved pressure. Thus, of thirteen cases in which death occurred from shock after the second stage, in seven by reason of failure to diagnose topographically, the pressure was not relieved directly over the seat of the lesions; whereas, in six cases in which a tumor of the brain was diagnosed and correctly localized, but in which removal was not attempted, owing to the size of the growth and other reasons, no patient died. The risk of an operation for decompression was greater if the opening for the relief of pressure was not made directly over the lesion. The treatment of shock must be arranged according to the symptosm which threatened life, the respiratory, the circulatory, and the body temperature. The embarrassment of the respiratory center, with its shallowness of respiratory movement and the typical Cheyne-Stokes respiration, was best dealt with by inhalations of oxygen until the effect of nutrient enemata began to make itself felt, but it was above all in depression of the respiratory center that strychnine was of use in combating shock. The heart did not require accelerating, but, as a rule, feeding, and repeated enemata of beef-tea and pancreatized milk were of service. If time pressed, a small dose of atropine was useful. Alcohol was to be avoided. Strong coffee was good. In certain instances, notably in children, one of the shock effects of operation was the losing of heat control and the temperature, instead of falling, rose and might become dangerous; this should be controlled by cold sponging of the upper limbs. In considering sepsis, in summary, he said he felt inclined to reassert the view expressed in 1886 that the less drainage was employed the better, and consequently that every effort should be made to close the skin wound as early as possible. An analysis of the Queen Square cases brought out the fact that where the technique of intracranial operations failed most was in the treatment of malignant disease. An accompanying table of 55 tumors was of great interest. There were 19 cases of glioma and 4 of sarcoma, a total of 23 cases, with recurrence within two years in 20 cases. There were 8 cases of endothelioma; 1 recurred three years later, the patient dying of valvular heart disease; 7 were alive and well, the longest 5 years. There were 4 tuberculous cases; 2 patients died within 3 months of tuberculous meningitis; 2 are alive and well, the longest 7 years. There were 8 cases of gumma, 4 cases of fibroma, 5 cases of cysts with no recurrences. There were 3 cases of adenoma and adenosarcoma with 1 recurrence. Unfortunately a large number of cases of cerebral tumor were essentially malignant, and by reason of their diffusing through the nerve tissues it was

very difficult to produce a complete and radical cure. Sir Victor thought he was justified in making the following general deductions on the question of surgical treatment of malignant disease of the encephalon: (1) That operation should be resorted to as early as possible; (2) that the tumor should be, if possible, freely exposed and examined and extirpated with surrounding tissue; (3) that if it could not be removed without undue interference with important or essential structures, there remained some possibility of the tumor undergoing retrogression in a certain number of cases.

SECTION ON OBSTETRICS AND GYNECOLOGY

First Day—Tuesday, August 21.

PRESIDENT, DR. A. H. FREELAND BARBOUR, OF EDINBURGH, IN THE CHAIR.

President's Address.—Dr. A. H. FREELAND BARBOUR of Edinburgh said that gynecology held out one hand to the general practitioner and the other to the specialist, more generous perhaps to the general practitioner caring for the growing daughter of the family, but equally at home in the company of the great operators. He dilated upon the relationship of gynecology to the work of the general physician, and said that he feared the student started out with a wrong idea because of the title given to the subject, that of "diseases peculiar to women," instead of being taught to apply to the branch the entire general knowledge of medical pathology. There was no pathological difference between appendicitis and salpingitis; epithelioma of the cervix did not differ essentially from epithelioma of the lip. He thought there was no reason why gynecology should be regarded as a specialty any more than obstetrics. A woman rightly expected to be attended for her gynecological troubles by the same physician who attended her in confinement, and it was then for him to say when she should pass out of his hands into those of the specialist in gynecological work. A man who devoted special attention to any one organ might become recognized as an authority, and was properly to be called in when the general practitioner recognized that he had a case beyond his power of diagnosis or treatment. He had found Canada ahead of the mother country in the teaching of gynecology to the general student, and believed that was the line along which advancement in the work was to be made. He likened the specialty to a peak in a mountain range for which it was necessary to have a broad foundation.

Concealed Accidental Hemorrhage.—Dr. A. H. WRIGHT of Toronto read this paper, which referred particularly to the discussion that took place on the subject of hemorrhage at the meeting of the Association two years ago, and which discussion he advised the younger men to read once or twice a year. The writer dealt particularly with concealed accidental hemorrhage, and believed that many such cases were overlooked, and were much more common really than had been supposed. He believed a large number of the sudden deaths in pregnancy were due to this cause. The symptoms to be looked for were sudden, sharp, cutting pain in the upper uterine zone, followed by continual dull ache, with increasing prostration. With such symptoms, until the uterus was emptied, the patient was in great danger. The writer believed that these symptoms were due principally to shock only, and not to loss of blood. He cited two cases. One was that of a woman of thirty-three years, in her fourth confinement; labor pains commenced at midnight; there was very severe pain at eight o'clock in the morning following, and at nine the woman was in a serious condition of shock, and was delivered at once; death occurred shortly after. The second case was that of a woman of thirty-four years in her third pregnancy; when seven months advanced she was seized with sudden severe pain in the abdomen while out driving; the condition was relieved with morphine and stimulants; four days later labor occurred, and a small clot, such as might have been produced by a pint of blood, was found. In referring to treatment, the writer considered accouchement forcé a very dangerous procedure; that in a case like the second it would have caused death. Friction of the abdomen, electricity, amyl nitrite, dilators, and the vaginal plug he condemned, and thought they should never be employed. He advocated the expectant plan of treatment, treating each symptom as it arose. Not less than a half grain of morphine should be given at first, and not more than one grain in an hour. The patient's head should be lowered and the temperature maintained by artificial heat. High enemata of salt solution should be used and small doses of strychnine, never large doses, which he considered very dangerous.

Dr. A. H. FREELAND BARBOUR of Edinburgh thought the same results could be obtained in many different ways. In Dublin he said the practice was to plug the vagina; in Edinburgh to rupture the membranes.

Dr. J. A. TEMPLE of Toronto said that, aside from the treatment of shock, it was his practice to rupture the membranes and allow the escape of the fluid to enable the uterus to contract better. He would not advocate the delivery of the woman while suffering from shock, nor did he believe in the Dublin method of plugging the vagina.

Dr. W. S. A. GRIFFITH of London, Eng., thought the question suffered by being separated from that of placenta previa, from which it differed very little. He thought it a common condition to a slight degree in the earlier stages of pregnancy, but it was in the later stages that it was dangerous. The principal thing was to empty the uterus, not as quickly as possible, but as safely as possible. Cases of the Braxton-Hicks description were very uncommon, and personally he had never seen one. Dilatation could be done with the fingers, and version and delivery performed easily in most cases. Vaginal section he considered the best surgical procedure. He had never done a cesarean section for the relief of the condition.

Dr. MURDOCK CAMERON of Glasgow thought the cases very uncommon. Everything in treatment, he said, depended upon having skill at hand early, which often could not be had. He thought the proper treatment was to empty the uterus. Plugging the vagina and administering morphine he advocated as a means of dilating the uterus, having counter pressure with a firm bandage. He did not think a cesarean section indicated.

Metrorrhagia from Conditions of the Uterus, other than Neoplastic Formations.—Drs. WM. GARDNER and J. R. GOODALL of Montreal read this paper, dividing the cases into two groups, simple and complicated, and the simple cases into inflammatory and arteriosclerotic. By simple was meant the cases characterized by uncontrollable hemorrhage at the menopause, the uterus alone being involved; by complicated was meant those showing these characteristics, but with chronic disease of the appendages or other organs. The paper treated only of simple metritis, and nine cases were reported, six inflammatory and three arteriosclerotic. The characteristics of the inflammatory group were swollen cells, hyaline protoplasm, vacuolated areas and changes in the connective tissue, widespread swelling of the fibrillæ with just a nucleus here and there, with isolated areas of small, round cells. In the arteriosclerotic type the mucosa was healthy, but there was tremendous fibrosis. Original drawings were exhibited to show these pathological conditions. In six of the cases there was history of retroversion and infection. Subinvolution was an etiological factor in most of the cases. The essayists questioned the theory that all cases were due to infection, but believed that muscular insufficiency was a factor in all cases. Hysterectomy was advocated in all cases of the arteriosclerotic type. They considered the changes in the uterine wall in fibroma of the uterus and inflammatory metritis the same, and that the hemorrhage was due to the same cause.

Dr. A. H. Freeland Barbour of Edinburgh agreed with the authors that the cases of arteriosclerosis were only to be treated by hysterectomy. They showed themselves clinically by hemorrhage, resisting all other forms of treatment.

A Study of a Consecutive Series of 146 Cases of Ventrofixation of the Uterus.—Dr. A. E. Giles of London, Eng., read this paper, which was based upon a series of six tables: (1) Uncomplicated Retroversion, comprising 47 cases; (2) Retroversion with Fixation, comprising 26 cases; (3) Chronic Retroversion and Diseased Appendages, 21 cases; (4) Retroversion with Fibroids, 13 cases; (5) Prolapse of the Uterus, 19 cases; (6) Total Procidentia, 20 cases. Three main points were considered; first, indications for operation; second, technique; third, the after results. As to indications, in the majority of cases in the first group no operation was advisable, as it was a transient condition. In the congenital form pregnancy was the best treatment. Not more than 5 per cent. of this group required operation. The indication would be failure of pessary to produce satisfactory results. The symptoms were backache, leucorrhea, and frequent micturition. The indication in the second class was pain, and these cases were foredoomed to failure under treatment with pessary. Indications in the fourth group were more obvious, there being an indication apart from the displacement. Failures, he thought, were often due to insufficient treatment; curettage should be done at the time of operation; disease of the appendages should be remedied at the same time, as should also cysts of the ovaries, etc. As to the effect on subsequent pregnancies and labors, of 73 cases seen from six months to eight years after operation, 24 forty years of age or over, 49 between twenty-three and thirty-nine, within the child-bearing period, 12 became pregnant, 3 miscarried. Seven went to full term. In no case was there tendency to postpartum hemorrhage. He believed there was slightly increased tendency to miscarriage. In ten of the twelve seen after pregnancy the uterus remained fixed. Ninety-five per cent. of the patients remained well, so far as the position of the uterus was concerned. The general condition was improved in 90 per cent. of the cases.

Dr. Wm. G. Gardner of Montreal said that it was only with the uncomplicated cases that the pessary was of any use. Many operations had been proposed, but none of them, to his mind, was equal to that discussed by Dr. Giles. The ideal result was the establishment of a sort of third ligament from the uterus to the abdominal wall, admitting of a degree of mobility, and yet maintaining the uterus in anteversion. The results of the operation were, of course, variable, and the essayist was to be congratulated on his very excellent success. The great bugbear, he thought, was the sclerotic or cystic ovary, which must be dealt with at the time of fixation. The repair of ruptured cervix and all plastic work in the vagina should be done at the same time. He considered that the operation was not to be blamed for the abortions or miscarriages following, as it was an unhealthy uterus that was operated upon.

Dr. J. A. Temple of Toronto preferred ventral suspension as giving a more normal, mobile position of the uterus. He employed two sutures, as described by Dudley of Chicago, one on either side, forming two normal suspensory ligaments. He believed with Dr. Gardner that the abortions were due to pregnancy occurring too soon after operation, while the uterus was still in an abnormal condition.

Dr. E. C. Dudley of Chicago had performed the operation of uterine suspension over five hundred times, and it was satisfactory, so far as systemic effects were concerned. He thought much of the criticism against suspension, as performed by Dr. Howard A. Kelly, was due to the fixation operation, in which the mobility of the uterus was interfered with. He had come to look upon the suspension operation, however, as not being an anatomical operation, and had lately been doing the operation of Dr. Gillean, somewhat modified in detail, which had given him very satisfactory results.

Dr. D. Tod Gilliam of Columbus, Ohio, said that his operation of internal suspension by the round ligament was not dangerous, as had been claimed by some; in the several thousand cases he had collected nothing of the kind had occurred. He believed with Dr. Dudley that we should do that operation which was most anatomical. Many of the so-called suspension operations were not suspensions, the uterus remaining fixed and immobile, and these patients on coming to pregnancy suffered greatly. In his operation the uterus accommodated itself to the movements of the body, and the results were more satisfactory from beginning to end. During pregnancy the round ligament grew and enlarged with the growth of the uterus, so that there was no impediment whatever to parturition.

Dr. S. M. Hay of Toronto expressed surprise at the essayist not making some distinction between ventral fixation and ventral suspension, the former of which should be reserved for cases beyond the possibility of conception. He believed that, as a matter of routine, curettage should be done, as there was usually a chronic congestion in these cases. His experience had been with fifty cases; in three there had been subsequent displacement. He had opened the abdomen after this operation four times for other purposes, and in each case had found the conditions the same as at time of operation. He thought the uterus should be well anteverted and the suspension made from the posterior wall.

Dr. Bovée of Washington, D. C., had thought that, as to the cases in the first table, retroversions uncomplicated had no symptoms, and that when there were symptoms they were due to complications. As to the distinction between retroversion with fixation and chronic retroversion with diseased appendages, his conviction had been that these cases were due to diseased appendages, and that the diseased appendages were the cause of the fixation. He deprecated the operation of fixation in women past the menopause; he believed that then the uterus should be removed. He considered fixation the substitution of one anatomical deformity for another. Vaginal hysterectomy he believed less dangerous than a ventral fixation.

Dr. A. E. Giles of London, Eng., in closing the discussion, said that the operation performed in his cases was an intermediate operation between a fixation and a suspension The abdomen was opened, a suture passed through the fascia and peritoneum of one side, then through the uterus, and back through the peritoneum and fascia of the other side. Another stitch, and generally a third, was made in the same way, but there was no scarifying. There was fixation to the fascia and muscular layer, and for that reason it had not been called a suspension. He considered that the important point was that the fundus was left free, because it was that part which was most enlarged in pregnancy. Shortening of the uterosacral ligament was an operation which he believed should be done more frequently.

Second Day—Wednesday, August 22.

Changes in Uterine Fibroids after the Menopause, with Special Reference to Operation.—Dr. Chas. A. L. Reed of Cincinnati read this paper, referring particularly to the coexistence of cancer and fibroids; 80 per cent. of all cases, according to the essayist, developed malignancy after the menopause. The writer advocated operative procedures in practically all cases, as the operation for fibroids, he said, yielded a mortality of less than 5 per cent. In operations after cancer had developed there was a primary mortality of 20 per cent., and the ultimate mortality was probably 100 per cent. He thought the following conclusions justified: (1) The only safe place for a fibroid of the uterus is outside the patient's body; (2) the menopause is a poor surgeon; (3) certain cases should be operated upon without regard to the menopause, as tumors of rapid growth, or when, by pressure, they interfered with the circulation of blood or the secretion of urine, or became the site of suppuration or malignancy; (4) the only cases in which there should be hesitancy as to operation were those in which there was no pressure or hemorrhage or which had

ceased to grow; (5) patients who chose to adopt a waiting policy should be advised of the danger, and should be examined at frequent intervals.

Dr. J. F. Ross of Toronto was sorry to hear the writer of a textbook draw his conclusions so rigidly. He thought there were a great many of the younger operators who sacrificed the lives of women by operating for small fibroids. He did not think the uterus should be removed simply for fear that cancer might develop. In many cases in which cancer develops, he believed it would develop whether the fibroid were present or not. He desired to protest against the rigid conclusions of the essayist.

Dr. Byford of Chicago disagreed with the essayist, and thought that the changes after the menopause that produced trouble were few. Many women, he said, died with fibroids without their ever having been suspected. He did not advocate operating at the menopause unless the tumor was growing rapidly.

Dr. Reid of Glasgow had watched fibroids for thirty years, such as one would now wish to operate upon, and he believed that if at the menopause a woman had a fibroid which was not very large, and which did not give distinct evidence of change in the way of growth, it was wise to let it alone. If, however, it continued to grow, it was unwise to postpone operation.

Dr. Murdock Cameron of Glasgow had never seen tumors disappear after the menopause, and did not believe in such a thing. There were tumors that tended to disappear under dissolving treatment, but they were not fibroid. He considered the most important question was that of diagnosis, which was not an easy matter. He believed that when the diagnosis had been made, the fibroids should be removed, unless there was some contraindication, as it was impossible to know what degenerative changes might take place in such tumors.

Dr. Wm. Gardner of Montreal reported a case of a woman with large fibroids, who married and passed through three confinements without complication or difficulty.

Dr. Marcy of Boston agreed with every one of Dr. Reed's conclusions. The secondary changes that occurred in these tumors were a menace. He had recently operated upon a patient with fibroids who was seventy years of age, showing that even at this advanced age the operation was not exceptionally dangerous. The years in front of such a patient, he said, were wearisome and without pleasure, and he agreed with the essayist that operation should be done early, especially in view of the fact that the mortality was less than 4 per cent.

Dr. Evans of Montreal cited a case in which he knew the tumor had disappeared. The patient, a woman of thirty, with a large myoma, was examined at frequent intervals for several years, and the tumor gradually disappeared, and she had since been delivered three times.

Dr. W. S. A. Griffith of London, Eng., said that it had happened to him twice in the last year to have to remove fibroids from women over seventy-one, and both were calcified tumors. He believed that the disappearance of fibroids after the climacteric was as certain as anything in medicine, and he entirely disagreed with Prof. Cameron on this point. Of course, when the fibroids increased in size it was necessary to remove them; otherwise they should be let alone.

Dr. Joseph Price of Philadelphia considered that fibroids were pathological and retrograde from their very inception, and that the patients were never well mentally, to say nothing of their other troubles. It would be impossible, he said, to exaggerate the multiple changes that occur in association with fibroids. He believed that the modern late marriages favored the occurrence of these tumors. He believed that all fibroids should be removed, and that when removed early, and in a good subject, the mortality was about *nil*. He expressed disappointment that there was such a divergence of opinion on the subject.

Dr. A. H. Freeland Barbour of Edinburgh agreed with the last speaker, and thought that every case must be considered on its own merits.

Dr. Reed, in closing the discussion, said that he believed that he was absolutely justified in saying that good results were always to be accomplished by reasonably competent operators in the uncomplicated cases. That there were incompetent operators should not deter one. He thought that those who simply showed in their discussion a general dissent seemed to affirm that a fibroid was not a dangerous thing and should be left alone, and that the menopause was a good surgeon. He thought that they had not given as much thought to their dissent as he had to his conclusions.

Indications for Cesarean Section.—Dr. H. L. Reddy of Montreal read this paper, the aim of which was to bring out a discussion as to whether or not the operation was justified for conditions of eclampsia and placenta previa. He thought that the operation should not be looked upon as a forlorn hope, but as a comparatively easy operation. He had known it to be done in a backwoods village by a country doctor twice on the same subject. He had operated fourteen times with one fatality. He advocated its performance much more frequently than it was done at present, and believed it to be the operation of election in certain cases of eclampsia and placenta previa. He said that symphyseotomy should be mentioned only to be condemned, as the integrity of the pelvis should not be interfered with when one could not be certain of the results.

Dr. A. McDermid of Chicago had twice done the operation for pelvic deformity, and with gratifying results, in saving the life of both mother and child. It was by no means a difficult operation. Within the past few months he had read a paper before the Chicago Gynecological Society, advocating the operation in placenta previa. There was less hemorrhage, he said in a cesarean section than in an ordinary case of labor. He also agreed with the essayist that in eclampsia it would afford the patient a better chance. He desired to emphasize the essayist's views as to symphyseotomy.

Dr. P. E. Truesdale of Boston added his testimony in support of the essayist's position. In 1903 he had read a paper before the Boston Obstetrical Society, reporting a case of cesarean section for placenta previa, and had been much criticised at that time. In this case there had been very little hemorrhage; time was allowed for contraction to take place, and when the placenta was removed only about a half ounce of blood was lost. As to technique, he advised against placing a ligature around the cervix, as it tended to cause a paralysis of the nerve supply and produce subsequent hemorrhage. He believed that in primiparæ in all cases of central implantation, and in many cases of marginal implantation, there was greater safety in this operation than in delivery through the vaginal route.

Prof. Murdoch Cameron of Glasgow had performed one hundred cases of cesarean section in the last eighteen years. He desired to say, however, that he had never seen a death from placenta previa. It was his experience that the os relaxed very easily in these cases and that there was no trouble in delivering. Therefore, he would hesitate to perform a cesarean section for this condition. In eclampsia it was different, and he saw no objection to the operation in a bad case.

Dr. W. S. A. Griffith of London, Eng., had had thirty-six cases, and had done the operation once for placenta previa. He was inclined to think that the only justification for the operation in eclampsia would be in the interest of the child; he could not see that it would be in the interest of the mother. It might also be performed in cases of cancer that were too far developed for hysterectomy to do any good. In cases of heart disease he doubted if the operation offered any advantages, as death was about as liable to occur after delivery in these cases as before.

Dr. Wm. Gardner of Montreal referred to hyperemesis gravidarum, where it was necessary to empty the uterus, and advocated vaginal cesarean section in such cases.

Dr. Reddy, in closing the discussion, said that it was his experience that in nine cases out of ten the placenta was attached to the anterior segment of the uterus, and so the hemorrhage was easily controlled. He believed the operation preferable to the vaginal cesarean section because of the lack of asepsis in that operation, and he would hesitate to do a vaginal cesarean section for hyperemesis gravidarum.

The Value of Conservative Treatment of the Ovaries, with Special Reference to Operation.—Dr. Joseph Price of Philadelphia read this paper. He said that after a quarter of a century of experience in pelvic surgery he was not yet convinced that the so-called conservative surgery for tuboovarian disease had any value. One could not overestimate the postoperative mischief following the attempts to save a piece of the tube or ovary. It had become fashionable, however, to do this so-called conservative surgery, though many patients had lost their lives from the sequelæ of such attempts. As to the usefulness of such operations, he believed it impossible, in amputating a tube, to leave it patent and functionating. He said that the efforts to correct the sequelæ of conservative operations on the tubes and ovaries had shortened his life. Most operators, he said, admit that from 80 to 90 per cent. of the cases was due to gonorrhea; that if one could blot out gonorrhea one would blot out gynecology, unless the sequelæ of bad obstetrics might keep it alive for awhile. In these cases of salpingitis and ovarian degeneration, then, it was folly to preserve an eighth of an ovary with the idea of conserving the reproductive function. He had done it hundreds of times, and not a single conception had ever resulted. Very rarely had conception occurred after multiple punctures. He could not, in the light of these sequelæ, see that such resections were justifiable. Most of the cases wound up in rest cures and asylums. He believed that the best operators were no longer urging such procedures.

Dr. F. F. Lawrence of Columbus, Ohio, thought it was in the idea that conservative surgery was for conception that the danger lay, as extrauterine pregnancy followed readily any destruction of the lining of the tubes, and it frequently followed the attempts at so-called conservative surgery of the tubes and ovaries. If it did not conserve the patient's safety in the present and in the future, he could not see that it was conservative surgery at all. He doubted if there was ever extrauterine conception except when there had been bilateral infection, and he believed that both tubes should be removed.

Dr. W. P. Manton of Detroit had been doing conservative surgery for ten years, following Dudley's work, and in 100 cases of conservative surgery of the appendages, which he had been able to follow, there had been but three return for operation. In 64 cases, careful bimanual examination at different times failed to show any pathological condition, and of these 64, 14 per cent. subsequently conceived. He thought there were many cases where resections should be undertaken and where the results would be eminently satisfactory. He maintained that one gets no more adhesions or subsequent suffering with conservative operations than when total extirpation is performed.

Lantern Demonstration of Degeneration in Uterine Myomata.—Dr. Thos. S. Cullen of Baltimore, Md., gave this exhibition, which consisted of over a hundred slides, showing almost every phase of pathological degeneration of uterine myomata. At the close of the demonstration, Dr. Cullen also showed the abdominal contour of a patient from whom an 89-pound myoma had been recently removed, the patient herself weighing but 85 pounds. The woman made a good recovery.

"A Catheter should be kept tied to the handle of every pair of obstetric forceps." By this statement a well-known teacher of obstetrics intended to impress upon his hearers the necessity for emptying the bladder before the instrument was introduced into the vagina.

THE AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Ninth Annual Meeting, Held in Boston, Mass., June 4 and 5, 1906.

The President, Dr. H. W. Bettmann of Cincinnati, in the Chair.

The Mutual Obligations of the Surgeons and Internists in the Proper Development of Gastric Surgery.—In this, the President's Address, Dr. Bettmann said that all surgical operations must be based on three factors: 1. The prognosis under medical treatment; 2. The immediate result of the operation; 3. The ultimate result of the operation. The internist must decide the first, the surgeon the second, and both the third factor. To find the truth, the sincerest co-operation was necessary. After referring to the fact that the practice of gastroenterology had been revolutionized during the past thirty years, both as regarded accuracy of diagnosis and directness of therapy, Dr. Bettmann said that the general practitioner had not kept pace with these advances, and that, as a result, many patients went from bad treatment to surgery. The surgeon should ask the patient not how long he had been treated, but how well. In referring to the statistics of various operators for the relief of cancer of the stomach, the speaker said that surgical conclusions should not be plucked before they were ripe.

Remarks on Banti's Disease (Splenomegalia and Cirrhosis of the Liver).—Dr. Max Einhorn of New York read this paper (see page 329).

Dr. J. Kaufmann of New York City said he thought the symptom complex given by Banti was at best not a very well defined one, and we should be very careful about applying it to cases, even if they did show some of the symptoms or a combination of the symptoms named by him.

Dr. I. Adler of New York City said that before making the diagnosis of Banti's disease, the complete syndrome must be present. It should be remembered that in Banti's disease there was a primary enlargement of the spleen, besides a rather peculiar blood picture.

Dr. A. L. Benedict of Buffalo said the very fact that the so-called Banti's disease was so rare militated against its being a clinical entity, because, according to the laws of chance, any symptom complex that was a clinical entity and not a mere coincidence must occur fairly frequently.

Dr. J. C. Hemmeter of Baltimore said that the most extensive account of the Banti syndrome was by Osler, who had reported the largest number of cases. In referring to the primary splenomegaly, the speaker said that in two of Osler's cases removal of the spleen cured the patients.

Dr. Einhorn, in closing, said that the cases he had reported presented certain symptoms. Whether we called them Banti's disease, or something else, was immaterial. In Banti's own description he included only those cases in which there was a benign tumor of the spleen of enormous size, together with enlargement of the liver, anemia and ascites. The cases ended fatally, unless the spleen was extirpated in the primary stage.

The Reflexes Controlling the Peristaltic Movements of the Esophagus.—Dr. S. J. Meltzer of New York City read this paper, in which he reported a series of experiments bearing on this subject.

Achylia Gastrica, with Report of Cases.—Dr. Franklin W. White of Boston read this paper, in which he reported a series of cases of simple achylia gastrica, illustrating its not infrequent occurrence as an independent condition, apart from gastric cancer or chronic gastric catarrh. In 183 cases of disease of the stomach, there were forty-one cases with less than normal acidity, and in nine of these there was an absence of all elements of the gastric juice, a condition of achylia gastrica; seven were primary cases, and two were secondary to chronic gastric catarrh. These cases were important because of their relative frequency (nearly 5 per cent. of this group of cases) and because of

the resemblance of some of them to gastric cancer. It was important to recognize their frequency because of the modern tendency to advise exploratory laparotomy in all cases which resembled cancer. The symptoms were not characteristic. The diagnosis was made chiefly from the physical examination of the patient, the gastric contents, and the feces. The condition of achylia persisted during the whole period of observation, from one to two years, in all but one case. In this one a return to the normal gastric secretion occurred, and had persisted up to date. It was often difficult to distinguish simple achylia from the early stage of cancer, or from well-developed cancer without stasis. The character of the stomach contents, the absence of occult blood in the stools, the absence of cachexia, and the permanent gain in weight under treatment, were the most valuable points in diagnosis. The chief indications for treatment were to improve the patient's general condition by hygiene, rest and tonics, to compensate for the loss of gastric secretion, and to protect the motor functions of the stomach. In most cases, diet without drugs was sufficient.

Dr. JOHN A. LICHTY of Pittsburg said there was one point in regard to which he differed with Dr. White, namely, the ease of recognizing achylia gastrica. It was a comparatively simple matter to make the diagnosis of achylia, *i.e.* an absence of gastric juice, but the diagnosis of achylia gastrica was not made so readily. Some of these cases followed a very peculiar course. The absence of gastric juice would at times follow a nervous shock or intense grief. Based upon a gastric analysis, we would call such a case achylia gastrica, but if followed up it would be found that the loss of the gastric secretions was only temporary.

Dr. J. KAUFMANN said he could confirm the statement of Dr. White that achylia gastrica was not an infrequent condition. The speaker thought we could understand the condition better if we did not speak of achylia gastrica as a disease *per se*, but merely as a symptom. It was a functional disturbance, which might be associated with many different conditions of the stomach.

Dr. WHITE, in closing, said that while in the majority of cases of achylia gastrica the diagnosis was comparatively easy, there was a minority in which it was very difficult indeed.

Hypersecretion, Associated with Cirrhosis of the Liver.—Dr. HENRY F. HEWES of Boston read this paper. He stated that the occurrence of disturbance of the stomach among the clinical manifestations of diseases of the liver and its appendages was a well-recognized phenomenon. In connection with this subject he reported three cases of gastrosuccorrhea or hypersecretion of the stomach occurring in association with disease of the liver, two in association with atrophic cirrhosis, and one in association with gallstones. The cases were of special interest in connection with the study of disturbances of the stomach, owing to the fact that in all the hypersecretion was the prominent feature at the time the cases first came under observation; in fact, in two of the cases it was so exclusive a feature that they would both have been considered as cases of hypersecretion of the stomach, pure and simple, of unknown cause, had not findings made at a later date revealed the presence of liver disease.

The Relation of the Kidneys to Gastroenterology.—Dr. A. L. BENEDICT of Buffalo, N. Y., in this paper discussed at length various renal conditions, and their apparent relation to alimentary disturbances. He stated that while almost any disease of any part of the body might occasionally produce or be accompanied by some definite disturbance of digestion, or call for special attention to diet and metabolism, the following partial classification of renal conditions was suggested as pertinent: 1. Mechanical influences, such as movable kidney, calculus disease, and urinary obstruction. 2. Chemic and allied influences, including acute and chronic nephritis, renal paresis and paralysis, polyuria, and urinary abnormalities secondary to digestive and metabolic disturbances without strict renal disease. The speaker referred to the significance of the relatively large number of cases of movable kidney he had encountered in digestive practice, and in the statistics he had collected he had considered as movable kidney only those cases in which the organ showed an unmistakable, palpable change of position, beyond anything that could be ascribed to elasticity of the abdominal wall. In his cases, no significant association with any particular digestive disease had been demonstrated, certainly not with inflammation of the appendix, nor with genuine gastroptosis. Among many hundred cases he had met with only two cases of hepatoptosis, and he had not been convinced of a typical general splanchnoptosis. He had found very few cases of movable kidney in a series of two or three hundred children, ranging in age from early infancy to puberty. In the correction of movable kidney, nephropexy often failed signally, and there was, perhaps, danger in cutting, even with needle wounds, excretory tubules. In many cases, the gastric symptoms associated with movable kidney seemed purely reflex, the physical and chemical examination of the stomach resulting negatively.

Dr. JOHN A. LICHTY said that since 1878 he had examined 4,778 cases. Among this number he had included a number of children, as well as other patients who were not suffering from gastrointestinal disturbances, and among the entire number he had found 809 cases of movable kidney. The speaker said he agreed with Dr. Benedict that splanchnoptosis was not a very frequent condition, even in association with prolapse of the kidney. The latter condition was far more frequently met with in the female than in the male, and seemed to be limited to the neurotic type of women, who were always below the normal standard of health. He had in mind one family where the condition existed in the mother and two or three of the daughters.

Dr. MAX EINHORN said he thought the recognition of the various ptoses of the viscera depended largely on what the individual regarded as a ptosis, and how the examination was made.

Dr. BENEDICT, in closing, said he thought the subject of the causation of movable kidney was a very complicated one, and he was convinced that the usual causes to which it had been assigned, such as tight lacing, etc., had very little to do with it. He looked upon it as a developmental defect. In several of his cases, the patients were born prematurely, although it was very difficult to gather statistics along that line.

Professor Fisher's Method of Estimating the Percentage of Proteids, Fats, and Carbohydrates in the Food.—Dr. A. L. BENEDICT gave a demonstration of this method.

The Gastrointestinal Disturbance Associated with Migraine.—Dr. JOHN A. LICHTY of Pittsburgh, Pa., said that in a paper read before this association in 1903, he reported 73 cases of migraine studied with reference to the associated digestive disturbances. Since then he had been able to add 108 to his list. Of the 181 cases, 155 were females; 26 males. One hundred and sixteen gave a distinct hereditary history. Ninety had a prolapse of one or more of the abdominal organs, most frequently of the right kidney. One hundred and thirty-seven gave a definite history of digestive disturbances between the attacks. The symptoms were definite, such as heaviness after eating, pyrosis, fermentation and gas, constipation or diarrhea. In 101 of the cases, in which gastric analyses were made, 25 had a normal secretion of gastric juice, 32 had an excessive secretion (hyperacid), and 44 had deficient secretion (hypoacid). Many showed the evidences of chronic gastritis and enteritis. A few gave the history and had the clinical evidences of chronic ulceration of the stomach. In correcting these abnormalities, very satisfactory results were often experienced. Dr. Lichty said he had for some years abandoned all the so-called specific treatment of migraine. There were two remedies, however, which he used

almost as a matter of routine when the removal of the reflex and exciting causes was impossible, or did not accomplish the desired results. They were the bromides and the various preparations of cannabis indica.

Influence of Rest, Exercise, and Sleep on Gastric Digestion.—Dr. Julius Friedenwald of Baltimore, in this paper, gave a brief review of the literature on the subject, which indicated that the results obtained by various observers were so conflicting that the question required further investigation. For that reason, certain individuals, two with normal digestive powers and eight suffering with various gastric disorders, were the subjects of this investigation. The individuals were examined after resting, after moderate exercise, excessive exercise, and after sleeping. From these observations, the following conclusions were reached: (1) In persons with normal digestive powers it made but very little difference whether the individuals rested, exercised, or slept after meals. (2) In patients suffering with superacidity and subacidity, it was best to rest after meals. (3) In patients suffering with motor disturbances of the stomach, it was best to prescribe moderate exercise after meals.

Appendicitis Larvata.—Dr. Alfred D. Kohn of Chicago, Ill., read a paper on this subject. He stated that Ewald, in a paper presented before the Congress of German Surgeons, in 1899, was the first to throw light upon this subject. He reported a number of cases which he termed, collectively, "appendicitis larvata," or masked appendicitis. None of the patients gave a history of appendicitis, yet a careful physical examination made it possible to diagnose chronic, subjectively unnoticed appendicitis, careful palpation disclosing a thickened, swollen mass in the region of the cecum. Dr. Kohn said that while no claim could be made that appendicitis larvata was a disease for itself, and with the full knowledge that it was merely a name for unrecognized chronic appendicitis, yet it was necessary to know that there were many atypical forms of appendicitis, the failure to recognize which was often responsible for the death of a patient who might otherwise have been saved by a correct diagnosis and operation. We were all too prone to call diseases we could not understand "nervous" diseases, for want of a better term. Appendicitis larvata and cholelithiasis accounted for many so-called nervous dyspepsias, and perhaps, as our knowledge broadened, we might account for the rest. The symptoms of appendicitis larvata were manifold, varying from attacks of simple indigestion to severe attacks of diarrhea. The stomach symptoms were especially prominent in the young. Attacks of belching or pain at irregular intervals after eating, alternating with freedom from gastric distress of any kind, in spite of the most liberal diet. Diarrhea was also a very common symptom, especially in the morning, with freedom from the same during the rest of the day.

Dr. Benedict said that personally he believed there was such a thing as typhlitis. The fact should always be borne in mind that the appendix was really an unexpanded portion of the cecum, and there were many cases of chronic inflammation of the bowel in which the appendix was taken out and the symptoms still persisted. If we had to deal with a typhlitis, we would not cure the condition by removal of the appendix.

Dr. S. J. Meltzer of New York City, while admitting that there were cases of so-called masked appendicitis which might be termed appendicitis larvata, said the fact should not be lost sight of, however, that if an abdominal pain disappeared after an appendectomy, it should not be taken for granted that an appendicitis had existed. There were certain conditions, such as tuberculous peritonitis, in which an exploratory operation was apparently beneficial, but we were still ignorant of the true significance of an exposure of the intraabdominal organs. The profound effects of such a procedure were well shown in the experimental work on rabbits, which was now being carried on. In the class of cases reported by Dr. Kohn, it was possible that not the appendix alone was responsible for all the reflex symptoms, but rather that it was only one link in a long chain. The speaker also again called attention to a method which he had found of great assistance in palpating the lower abdominal organs, namely, contraction of the psoas muscles. In some cases of appendicitis and sigmoiditis, another helpful sign was the referred pains, which, as a rule, were confined to the side where the lesion was located.

Dr. John A. Lichty said it was often difficult to decide whether to advise operative interference in cases of right-sided abdominal pain where the lesion was of a doubtful character.

Gastric Ulcer in Childhood.—Dr. Harry Adler of Baltimore, Md., reported a case of gastric ulcer in a girl of eight years, and referred to the comparative rarity of this condition in childhood, according to post-mortem statistics. In 390 autopsies at the Baby's Hospital in New York, Martha Wollenstein found five cases of gastric ulcer. Holt reported three cases accompanying follicular gastritis, and five accompanying general tuberculosis. As to its occurrence clinically, Booker, Rotch, Griffith, Louis Starr, and Koplik had never seen a case that they recognized. Koplik reported one case seen at autopsy, accompanying empyema. Jacobi stated that it was not uncommon in children from seven to thirteen years. Fenwick recognized five varieties of gastric ulcer: Hemorrhagic erosions, follicular ulceration, tuberculous, malignant and simple ulcers; the last might be either acute or chronic. As regarded the symptoms, hematemesis was the most prominent, and was noted in 40 per cent. of the cases in which histories were obtained. The blood was bright red, and varied from a few streaks in the vomited material to considerable amounts. In four acute cases it was the immediate cause of death. The diagnosis depended largely on the presence of blood in the vomit or stool, but care must be taken to eliminate the many other causes of hematemesis and melena. In infants, the blood might arise from the gums, nose, throat or lungs, and be swallowed, followed by vomiting. Blood might be sucked from the breasts of the mother, or, in neonats, had been swallowed during parturition. True hematemesis might arise from a number of causes other than ulcer. It had been observed in purpura, hemophilia, scurvy, and similar diseases in which there was a tendency to bleeding from any of the tracts. Cirrhosis of the liver, a not very common condition in children, might give rise to it. In malignant forms of the exanthemata, notably measles and variola, it was likely to occur. The speaker said he had seen it in a case of influenza. Other causes were corrosive poisoning, severe retching (as might occur in pertussis), and traumatism due to swallowing of foreign bodies.

Dr. Max Einhorn of New York mentioned a case of gastric ulcer in a girl of twelve years, who made a good recovery under the rest treatment.

Recent Studies in the Diagnosis of Gastric Ulcer.—Dr. J. C. Hemmeter of Baltimore, in this paper, referred to points of differentiation between gastric ulcer and carcinoma, gastralgia nervosa and cholelithiasis, and spoke of the similarity of the objective and subjective signs and symptoms in some of these conditions. As an aid to diagnosis, he mentioned the value of the detection of occult hemorrhages by examination for blood in the feces. He also detailed a number of experiments on animals demonstrating the feasibility of producing lesions of the gastric mucosa, which could be made visible to the *x*-ray by first feeding the animal with a suspension of bismuth subnitrate. He also referred to Dr. Murdoch's method of administering orthoform as a valuable aid in differentiating between the pain due to gastric ulcer and that originating from gall stones. The drug would usually have a prompt effect in relieving the pain in the first condition, but was of no avail in cholelithiasis. In reply to the question of whether gallstones were visible by the *x*-ray, Dr. Hemmeter said they had given the method a trial, not only in subjects who had

gallstones, as shown by operation, but also with gallstones outside the body, and the results were entirely negative.

The Subsequent History of Thirty-two Cases of Chronic Gastric Ulcer Previously Reported.—By Dr. F. H. MURDOCH of Pittsburg. Of these patients, two had since died, one from aneurism of the aorta, another from hemorrhage from a recurrence of the ulcer. Of the remaining thirty cases, twenty were permanently cured, four were much improved, three were not improved, and three had not been heard from.

Dr. G. W. MCCASKEY of Fort Wayne, Ind., said that in a paper which he had recently read on this subject he made the assertion that in about 80 per cent. of all cases of gastric ulcer, surgical treatment was not called for from any point of view. In the remaining 20 per cent. there was a certain proportion in which surgical intervention should be advised. The speaker said he did not believe—contrary to what appeared to be the prevailing opinion among surgeons to-day—that a gastric ulcer was any more completely or permanently cured by gastroenterostomy than by medical treatment. That point remained to be proven by the surgeons.

Dr. MURDOCH, in closing, said that in the treatment of gastric ulcer by surgical methods, it was entirely useless to do a gastroenterostomy unless a stenosis of the pylorus existed. The experiments of Dr. Cannon had shown that, notwithstanding the presence of the artificial opening, the food would still continue to pass through the pylorus.

Demonstration of Gastric and Intestinal Movements.—By Dr. WALTER B. CANNON of Boston. For the purposes of this demonstration, which was given in the Physiological Laboratory of the Harvard Medical School, a cat had been anesthetized, and after the destruction of its spinal cord up to the neighborhood of the phrenic nuclei, the animal was immersed in warm physiological saline solution, and the abdomen opened. Gastric peristalsis, segmenting movements in the small intestine, and antiperistalsis of the proximal part of the large intestine, could thus be directly observed and studied. The method of demonstration was that of Bayliss and Starling. Dr. Cannon said the antiperistaltic movements continued so long as there was food entering the colon. They passed over the colon whenever a new mass of food entered the large from the small intestine.

Spontaneous Rupture of the Colon from Violent Peristalsis, with Report of a Fatal Case.—Dr. G. W. MCCASKEY of Fort Wayne, Ind., related the case of a woman, 42 years old, who gave a history of chronic constipation and headaches, associated with disturbances of the digestive tract. Her symptoms, which were of long duration, gradually increased in severity. At times, the peristaltic waves could be distinctly seen through the abdominal wall. A laparotomy was done, which revealed nothing abnormal in the abdominal cavity. In the pelvis, a diseased ovary and tube were found and removed. Several months later, during which period the patient had been fairly comfortable, she partook of an unusually full meal one evening, which was followed by indigestion. On the following morning, while she was not undergoing any exertion, she was suddenly seized with a violent pain, and rapidly went into collapse and died. Her death proved to be due to a rupture of the splenic flexure of the colon, through which the intestinal contents had escaped. There was some narrowing of the colon, but no evidences of a neoplasm.

Dr. A. L. BENEDICT referred to a rather unusual cause of rupture of the gut that had come under his observation. In certain foundries where radiators were manufactured, air blasts at high pressure were employed, and he recently saw an autopsy performed on a man who had been subjected to this high pressure through his clothing. The air-blast had entered the rectum and produced a rupture of the bowel at the lower part of the splenic flexure, with fatal results. Two similar cases had been reported in the lay press, one from Chicago, the other from a small town in New York. In all three instances the lesion was fatal, and in all the air was turned against the anus as a practical joke, without criminal intent.

Dr. S. J. MELTZER said that cases of the type reported by Dr. McCaskey had been described in literature, and in seeking an explanation for them it was not necessary to invoke the aid of an organic lesion. A small section of the gut into which a certain amount of air or fecal matter was compressed by two opposing forces, must rupture if the pressure was not relieved, and that could occur without the presence of an anatomical lesion.

Dr. MCCASKEY, in closing, said he could not speak positively regarding the narrowing of the gut in the case he had reported. Possibly, it was a congenital condition. The only thing that could not be excluded was a degenerative process of some sort; to discover that it would have required a histological examination, which was not permitted.

Habitual Constipation Viewed from the Standpoint of Modern Evolution of Dietetics is a Physiological Phenomenon.—Dr. C. D. SPIVAK of Denver read this paper

(See page 335.)

Dr. MAX EINHORN said that Dr. Spivak had referred to good teeth, slow eating, etc., as causes of constipation. Personally, he did not think they could be regarded as real etiological factors, because it was no doubt originally intended that the human being should have good teeth. The reason why so many people had to depend on false teeth was that they were brought up on a faulty diet, and did not make enough use of their natural teeth.

Dr. S. J. MELTZER mentioned the case of a man whose bowels sometimes moved only about once every four weeks; this had continued for years, and he had apparently suffered no ill effects therefrom.

Dr. G. W. MCCASKEY said he could not quite follow Dr. Spivak to his ultimate conclusions. He thought there was a good physiological reason for expecting an emptying of the bowels once a day, although he did not wish to imply that a failure to do this would be followed by serious consequences. We might meet with remarkable instances of constipation, like the one mentioned by Dr. Meltzer, where the failure to empty the bowels was apparently not followed by any untoward symptoms, but the average individual took his food three times a day, and under strictly physiological conditions that food would serve its purpose, and its indigestible residue would be ready for expulsion in about twenty-four hours. The too long transit of the food through the intestines gave more opportunity for the production of toxins, which were undoubtedly the cause of many of the chronic ailments to which the human race was subject. The diet of our day was undoubtedly conducive to constipation.

Dr. JOHN A. LICHTY referred to the interesting experiments of Pawlow on the glands and ferments of the digestive tract, which strikingly showed the delicate arrangement of the glands, especially in the first portion of the bowel. The speaker thought it would be a good idea if Pawlow's deductions were printed and pasted on every pill box and package that came from the manufacturing chemist. It would at least impress upon the physician the enormity of his offense when he disturbed the delicate mechanism of that region by the indiscriminate use of purgatives, etc.

To Prevent Germs in the deeper layers of the patient's skin from contaminating operation wounds Herff recommends the following procedure: The skin is anointed with a 1 per cent. iodine ointment in vaselin to which enough potassium iodide has been added to make the iodine soluble in water. Wherever fluids penetrate the film of vaselin they come in contact with the iodine, the antiseptic properties of which are well known. The protection may be made still greater by preliminary painting of the skin with 10 per cent. solution of iodine in alcohol.

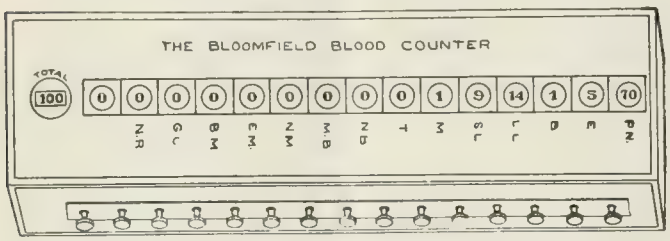
New Instruments.

A NEW HEMATOMETER.

By M. D. BLOOMFIELD, M.D.,

NEW YORK.

I BEG to present to the profession this hematometer, which counts the red and white blood corpuscles, also their different varieties, giving below the sum total of the reds and whites respectively. It is a very simple mechanism, consisting of a set of disks which are numbered consecutively to the highest average number of each particular variety. As soon as the total comes to 100 the bell rings and the differential count can be read right off. For convenience, the slip containing the classification can be easily changed if desired to correspond with the one usually followed by the examiner. The instrument, made by George Tiemann & Co., is well shown in the accompanying illustration.



The instrument is 8 inches in length and weighs about 9 ounces; is absolutely accurate, portable, and durable, and requires no skill nor technique in its use. As each number is turned up a click is heard, and the decided inconvenience of withdrawing the eye from the microscope to jot down the figure, or the necessity of having an assistant to mark down the figures, is overcome. For the busy microscopist this instrument, I hope, will prove invaluable.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 25, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	589	151
Diphtheria	158	14
Measles	51	7
Scarlet Fever	46	1
Smallpox	3	—
Varicella	4	—
Typhoid Fever	101	22
Whooping Cough	27	8
Cerebrospinal Meningitis	9	10
Malarial Fever	.....	.....
Totals	988	213

The Clinical and Pathological Importance of Chronic Pancreatitis.—A. W. Mayo Robson states that the relation of the pancreas to diabetes is now generally recognized. However, to wait until glycosuria develops before making a diagnosis is to throw away the patient's only chance of recovery. In nearly all cases, if treatment is instituted early enough, the patient may be restored to perfect health, and a fatal, lingering illness will be avoided. Pathological changes may originate in any of the constituent parts of the pancreas. The effects on the anatomy and functions of the organ will vary, according to the structures which are primarily affected and the nature of the change. Histologically the results of chronic inflammation of the pancreas may be divided into three classes: chronic interstitial interlobular pancreatitis; chronic interstitial interacinar pancreatitis; and cirrhosis of the pancreas. The writer then discusses the etiology of this affection. The onset of the disease varies with the cause. If it is due to obstruction of the common duct by a gallstone, there will be painful attacks in the right hypochondrium, associated with jaundice and possibly with fever of an intermittent type. In certain cases a swelling of the pancreas is noticed, due to enlargement of the head of the gland. Though usually present, pain and tenderness may be little marked, although sometimes the suffering is severe. Jaundice is not necessarily present at first. Dyspeptic disturbances are constantly associated with affections of the pancreas. In many cases of pancreatic disease excessive wasting is a prominent symptom. The frequent, bulky, soft, white motions, so typical of advanced pancreatic disease, owe their bulk partly to the abnormal quantity of undigested material, and partly to the excessive fermentation. A useful diagnostic point is the presence of alimentary glycosuria. In many pancreatic affections there is a tendency to general hemorrhage from wounds, or from mucous surfaces, and to petechial hemorrhage in the skin, or to more extensive bleeding in the subcutaneous tissues. There is often a considerable degree of anemia noticed in these cases of chronic pancreatitis. The diagnosis of this disease is not usually very difficult, although no one symptom can alone be relied upon as diagnostic. The prognosis of chronic interstitial pancreatitis surgically treated is very favorable if the case is taken in time. A marked hemorrhagic tendency generally heralds the near approach of a fatal termination. Preventive treatment is most important. Rational treatment should aim at the cause, whatever that may be.—*The Edinburgh Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending August 25, 1906:

THE MYSTERIES AND SOURCES OF SUICIDE.*

BY GEORGE M. GOULD, M.D.,

PHILADELPHIA, PA.

CLASSIFICATION OF THE CAUSES OF SUICIDE.—As examples of the classification of the presumed causes of suicide, we may take 9,179 cases in Prussia, occurring from 1873 to 1875, as given by Morselli: 1, mental disorders, 269; 2, unknown and diverse, 185; 3, weariness of life, discontent, 121; 4, vices, 109; 5, remorse, shame, fear of condemnation, 104; 6, physical diseases, 61; 7, afflictions, domestic troubles, 49; 8, financial disorders, 36; 9, passions, 34; 10, misery, 32.

Skelton's table of 508 cases is as follows: 1, unknown, 176; 2, remorse, shame, 103; 3, insanity, 60; 4, anger, quarrels, 43; 5, satiety of life, 22; 6, ulterior motives. 12; 7, vice, 12; 8, grief, 12; 9, bodily affliction, 11.

De Greef thinks the principal social conditions causing suicide in the order of their importance are: 1, poverty; 2, family difficulties, and 3, physical suffering, of about equal power; 4, alcoholism; 5, fear of legal persecution; 6, love, jealousy, and debauchery. Or in general: 1, physical and psychical disturbances; 2, economic difficulties; 3, genetic troubles; 4, moral difficulties.

As an example of the extent to which vaporous and unreal philosophizing may go, one may note Durkheim's theory of the three types of suicides: (1) The egoistic, *i.e.* those due to the morbid development of individualism; (2) the altruistic, *i.e.* the predominance of society over individuals; (3) the anomic, *i.e.* those due to the independence of the individual from moral restraint; social control is lost and individual desire is unlimited.

In brief, the more vague and generalized the naming of the supposed causes, the more worthless and useless. Durkheim thus helps not at all, and if in Skelton's list the errors are omitted, his classes 6, 5, and 2 might as well be added to class 1, and thus more than three-fifths of all might more conveniently be entitled "Unknown." It is evident that the truth as to motive and ultimate causes cannot at present be reached in any adequate or scientific sense. The facts individually are beyond us and our curiosity, personal or scientific, except in a minority of cases. I have for a long time been gathering the newspaper reports of the suicides occurring in the neighborhood of Philadelphia and New York, and the study of the gathering makes one feel the utter worthlessness and contradictions of the results of the older tabulators. The result of my attempts to group the definite and certain causes into classes may be summarized as follows: If 100 is made to represent the total number of cases of suicides from all causes, these proportions, roughly, would be they that are the most evident and certain sources, motives, or reasons of the deaths: 20, ill-health, physical and psychical, the latter much less important, and less accurately or definitely ascribed, than the first; 12, sexualism, including passions, illicit and unrequited love, disappointment in love, death of the loved one, etc.; 8, following murder, quarrel, injury to others, the result of hates, grudges, quarrels, etc.; 6, loss of property, social position, failure in ambition, etc.; 5, domestic afflictions, misfortunes, failures; 4, aimlessness, unideality, satiety of life, boredom, emptiness of mind or heart; 3, to avoid exposure after crime; 1, inability to conquer vicious habits—alcoholism, drugs, etc.; 41, unknown, or too indefinite to classify.

The *Chicago Tribune's* report for 1905 thus classifies the reports of the causes of the 9,982 cases of suicide of the year in the United States: Business losses, 32; liquor, 375; ill-health, 411; unknown, 721; disappointment in love, 958; domestic infelicity, 1,525; insanity, 1,826; despondency, 4,134.

The folly of the newspaper reports as regards the item "insanity," "during temporary insanity," etc., practically throws this class over into that of the "unknown." If the larger portion of the "despondency" cases is added to the "ill-health" class, the results are not very dissimilar to my own independently made classification.

Secret Drug-taking, Tobacco, Etc.—There are several factors, by their nature, and at least up to now unrecognized, and that in great part will remain undetected, which make this close and fairly accurate diagnosis much too faulty and misleading. Alcoholism, of course, and secret drug habits, as well as excessive use of tobacco, are in all probability the unknown precedents and real causes of a number of the suicides ascribed to cruder secondary and mediate causes supposed by the reporters to be the genuine ones. What rôles tobacco, secret drugging,* and drinking are playing in producing the diseases and suicides of civilization is a terrifying question, which must be answered by civilization in some way. But with all due allowance made, the pathogenic and suicidal parts they play are far less potent than two others hitherto unsuspected and unmentioned.

The Ultimate Sources of the Illogicalities of Suicide-statistics.—To the observant student it is frequently evident that the supposed causes, reasons, or motives of the suicide are palpably incorrect. Quarreling, anger, disappointments, thwarted ambition, poverty, imitation, boredom, psychic diseases, whim, even sexualism and alcoholism, are often only pretexts hiding deeper grounds, the innocent executioners, in fact, of precedent ignorances and mis-

*Epitome of a paper to be published in "Biographic Clinics," Vol. IV.

* Only one brought in close contact with the facts knows the extent of secret drug-taking. Among professional men the physicians head the list of suicides in the United States. Doubtless a large number succumb by the slower and unknown method of suicide through cocaine, morphine, etc., and probably another proportion by the quick and recognized method classed as suicide proper. The drugs are at hand in both cases. The negroes of the South are much addicted to the use of cocaine.

takes, and of inabilities to meet the challenging circumstance. They directly contribute and are charged with the crimes of more elusive and genuine causes and necessities. They produce the great body of the monotonous and unvarying minimum of cases of any social group. But the puzzling mysteries of suicide statistics consist of other factors which so far have eluded the curiosity and study of the statisticians and philosophers. These inexplainables are: The increase of suicide *pari passu* with advancing civilization; the high urban rate; the strange influence of occupation; the variability of the rate in different social groups; the relative male and female rate; the high rate in the unmarried and divorced, especially of males; the perplexity of age-incidence; the dependence of the rate on school-pressure and education. All of these mysteries, I think, are at once resolved by the influence of two diseases hitherto unobserved and hence not brought into the reckoning. All investigators have been unwittingly seeking the hidden variants which are at work beneath the illogic of the figures and which have turned the study into a disheartening mystery of contradiction, or a ludicrous chaos of unscience. These secret variants are venereal disease and the systemic effects of eyestrain.

The Rôle of Venereal Diseases.—The estimates made by the most expert syphilographers of the number of American citizens afflicted with the two forms of these diseases vary greatly, some saying that it is as low as 40 per cent., others as high as 80 per cent. If the lowest is the more accurate, the lesson is sufficiently horrifying. According to the 1906 report of Messrs. N. W. Ayer & Son, there are over 23,595 newspapers and periodicals published in the United States. The larger portion of these, and especially those of the town and country districts, have derived a great part of their income from the advertisements of quacks and nostrums, the very nature of which may hardly be described in decent language. Every genitourinary and gynecological specialist, as well as most general physicians, well know of the myriads of tragedies caused by these diseases and fostered by the wretches who delude their victims. The nature of these physical infections is such that the minds of the sufferers are easily and often made morbid and introspective, and to such a degree that the hidden shame, doubled by the deceptions of the quacks, renders these patients more secretive. Finally the burden can be borne no longer, and the number of suicides from erroneously stated or "unknown" causes is thus increased. With every advance of civilization there is an increase of those afflicted with these infectious diseases; urbanization is an infallible method of adding to the number; the fact throws a lurid light upon the higher suicide rate of the male everywhere existing; and upon the higher rate among the single than among the married, and upon the still higher rate among the divorced and widowed. The ramifications of these diseases are infinitely subtle and hard to trace, but as surely continuously present and permeating everywhere, among the innocent as well as among the guilty. Evade and avoid the duty as much as civilization may, there is no escaping it, and government and an enlightened public opinion must finally grapple with the problem in most serious and effective earnest.

The Influence of Scoliosis on the Suicide-rate.—Five experts examined thousands of school children in five large European cities and they found on the average that, by fourteen years of age, 27 per cent. had lateral curvature of the spine. Undoubtedly a larger number have the deformity undetected and in its functional stages. The school children of the United States, beyond question, have the deformity just in proportion as the number of school-houses, the degree of school pressure, approximates the central European models. Wherever there is lateral curvature of the spine there is a tendency toward, or full realization of, humpback, a defect that lessens chest-expansion, and aeration of the blood, and increases pulmonary tuberculosis, pneumonia, etc. As I have already said, "the terminal diseases seize upon the anemic, morbid, and devitalized scoliotic, and the terminal diseases occupy the minds of the pathologists and physicians to the exclusion of the early, real, and hidden causes." "The organic diseases are often merely the executioners of long precedent functional diseases." The peculiarity of scoliosis is that the slighter and more functional the disease, the more the suffering, the more disabling the reflexes and results. Another peculiarity is that in a practical sense profession and public have wholly neglected the disease in its functional and curable stages. No one examines the back in diagnosing a hundred morbid conditions resulting from back-strain, and only when the morbid curves are established and bony changes have taken place is the incurable curvature brought to the orthopedic surgeon.

If an erect being like man has the single small column supporting the trunk kinked or curved, the result must be pernicious. All the laws of poise, of anatomy and physiology are disturbed, distorted, and morbidized, resulting in many and any types of neural, cerebral, spinal, and reflex diseases. It may be that some of the greatest curses of civilization, such as epilepsy, insanity, "neurasthenia," etc., will be found due to these spinal deformities, too slight and functional to have arrested attention.

There can be no question that in the 27 per cent. of the young afflicted with scoliosis the disease is due almost wholly to two causes: (1) by the morbid writing-posture, which, by the absolute laws of spinal mechanics produces the morbid functional curves of the neck and vertebral column; and (2) by such optical defects of the eyes as necessitate habitual head-tilting in order to see plainly the most common vertical lines of print, etc. Either cause, alone or conjointly, will set up the lateral curvature and the kyphosis, at first functional, then slowly becoming organic. The laws governing the pathogenesis of these diseases I have elsewhere set forth. Now it is most noteworthy that the disease-producing writing-posture is also wholly of ocular origin, so that spinal curvature, this great source of human suffering, owes its origin to the "scientific" and professional inattention to simple ocular laws. The essence of the matter is that the mysterious and supposedly incurable suffering of many kinds, persistent, varying, weakening, harassing, inscrutable, and maddening, due to slight malcurvature and morbid function of the spine, spinal cord, etc. (the sole "trunk line" of communication between the head and extremities), is directly and indirectly the source of a great deal of suicide. It is first, and besides, the source of things worse than suicide, but by the very nature of the disease it must frequently provoke that sense of failure and despair out of which suicide must always spring.

Note, now, this: Spinal deformity, springing from the morbid writing-posture, as it were, born in the schools, must be in the largest part produced by civilization, increased by every advance in civilization, by urbanization, by sedentary occupation, by every additional hour devoted to the education process, etc.*

* A wise bookkeeper, when I told him he must have curvature of the spine, said, "Oh, I suppose so; I never knew an old bookkeeper who did not."

Diseases Consequent Upon Eyestrain, other than spinal curvature and its effects, are precisely of the kind to produce depression and despair. It is the mysterious, unexplainable, nagging, never-ceasing or ever-renewed pursuit of fate, the illogical and undeserved series of calamities, the unknown and incurable diseases which wear out hope and resistance, and finally land us in the deaths of the morbidity-table or of the suicide columns. Even if a name is attached to the disease which is killing us, a name that tells nothing, explains nothing, does nothing, that is comforting, and one goes smilingly to death, as in "consumption," "Bright's disease," etc. But when neither ourselves nor the best physicians can tell even what ails the patient, and cannot cure or cures end only in recurrence and recurrence again, then hope is lost and black melancholy follows. Spinal curvature in its incipient and its functional stages, with its host of sequent and distant nervous and morbid effects, is of the hidden and relentless kind to bring the patient to despair. The very existence of the vertebral anomaly is unknown, either by patient or physician, and it is thus a capital illustration of an unknown, unseen enemy in the dark, tirelessly pursuing.

But of all the diseases that have afflicted humanity since modern civilization began, the other nameless and indescribable, mysterious and ever varying ones classed as "migraine," "neurasthenia," "bilious attacks," "sickheadache," "dyspepsia," and a score of other names, seem, with diabolic cunning, designed to conquer all human resistance and heroism and wear the sufferer to utter despair.

Take "headache," "migrane," or "sickheadache," there is no family but has its victim, even after the disease has been known to be due to eyestrain for thirty years. There is no adult that cannot remember one or more instances of the awful and life-long sufferings of parents, grandparents, uncles, aunts, etc. Many can now see how the tragedies of the olden times were due to this grievous affliction. One can go into any village or city of the land and demonstrate the existence of the disease in varying degrees and types in from 25 to 50 per cent. of the inhabitants. A great authority says, "The nature of the disease is unknown"; the doctors cannot cure, not even the majority of the oculists. And yet there is no more doubt in the minds of the competent that 95 per cent. of these patients can be cured, than that breathing stops with death. All of the symptoms of this disease are produced by use of the eyes; they cease when reading, writing, etc., is stopped, are wholly cured with scientific spectacles, etc., but the ever-renewed round of headache, vomiting, depression, insomnia, constantly increasing weakness, weariness of life, and the rest, alternating with short periods of apparent health and happiness—these are the things which prepare the way for death by the hand of other diseases, or by one's own hand.

A more authoritative judge does not live than Dr. John H. Musser, of Philadelphia, Ex-president of the American Medical Association and Professor of Medicine in the University of Pennsylvania. In an article read at the meeting of the American Medical Association last year and published in the Association's Journal, Professer Musser states: "*The Eyes.*—The subject is familiar to all; who has not seen correction of errors of refraction relieve so-called bilious attacks, periodical vomiting, anorexia, indigestion, and other gastric symptoms? The cure of grave organic ocular defects relieves similar gastric conditions." A great American surgeon says his most brilliant cures in cases of threatened appendicitis and other surgical abdominal diseases have been by and through the oculist, thus avoiding the operations of the surgeon.

The indigestions and the dyspepsias, the disorders of nutrition, lie at the foundation of the diseases which lessen and kill the power-supplying forces of our life. Headaches are the evidences of diseased neural, cerebral, and mental control. The great, certainly the vast majority of these two classes of diseases are caused by eyestrain, and in this fact one has the explanation of the hidden source, the secret variant which makes clear the mysteries of suicide. If there is added the neurasthenias, the disorders of the mind and nervous system, directly due to the difficulties and strains of vision as demanded by civilization, we have the solution of most of the mysteries, illogicalities, and anomalies which have tormented the statistician of suicide. Taking each of these mysteries in turn we find:

Civilization and the Suicide-rate.—The reason for the fundamental law of the disproportionate increase of the suicide-rate caused by civilization itself is made clear, for every step of that advance we call civilization is conditioned upon that greater use of the eyes in writing, reading, and "near-work," whence eyestrain and its morbid effects spring. The scientific glasses which will absolutely neutralize this eyestrain can be supplied, but, except in a few cases comparatively, such correct optical helps have not been provided. In all Europe it is almost impossible to get them, and in the largest part of America.

The High Suicide-rate in Cities.—The cities are the great foci of that life which necessitates the most near-work of the eyes, in commercial, mechanical, and educational life, and hence the suicides provoked by spinal, cerebral, and digestional diseases are doubled or trebled in the cities. Confinement in rooms and sedentary occupations, city-life, in a word, increases the crowd diseases, especially the infectious ones, pneumonia, tuberculosis (consumption), typhoid, etc.; but not only does the consumptive not commit suicide, he is proverbially hopeful. Indeed, those continuously ill, dangerously ill, especially if their disease is named and supposed to be known, not mysterious and of unknown nature and origin—these do not commit suicide. Only those up and about but ailing, struck down for a time, and ever thus alternating between severe illness and temporary health—such are they who are driven to despair. They are the migrainous, the neurasthenic, the headache, and bilious, and "nervous" sufferers, and their diseases are almost always due to eyestrain and spinal curvature.

The Occupation Rates.—The suicide-rate, except in soldiers and vagrants, exactly corresponds to, and is mathematically increased by every occupation just in proportion to the use of the eyes required by that occupation, at close range, such as is shown in the tables. Take that of Morselli, of the suicides in Italy, 1866-1876, per million individuals: (1) dependents, and without profession, 8; (2) production of raw materials (out-of-door laborers), 25; (3) industrial supernumeraries (day-laborers, etc.) 30; (4) religion (in Italy, to be noted), 45;* (5) industrial productions, 56; (6) domestic servants, 68; (7) fine arts(?) 94; (8) property, movable and immovable, 113; (9) transport, 154; (10) medical profession, 163; (11) instruction, education, 175; (12) jurisprudence,

* That the rate among the religious orders and priests is low is principally explained by the little amount of ocular labor at near range done. Protestant clergymen have a higher rate, but one still below that of other professions, not demanding so much literary work. Parochial duties, like any others that lessen ocular labor, lessen the mortality, morbidity, and suicide rates.

217; (13) commerce, 246; (14) vagrants, 259; (15) public administration, 324; (16) letters and science, 618.

The Rates in Different Countries.—Every country's condition as to the causes that produce suicide is peculiar, and especially is that of Italy exceptional, but the law in each and all is the same: The suicide rate, soldiers and tramps excepted, is exactly in proportion to the use of the eyes at work at from 12 to 18 inches distant from the object, *i.e.* in reading, writing, handicrafts, etc. And each country's rate, as compared with that of another, regardless of race, religion, etc., is also in exact relation to the use of the eyes as stated.

As to the higher rate in males than in females, the consequences of venereal disease and of responsibility are here manifest, but of still greater importance is the fact that that use of the eyes which causes eyestrain and its effects is more imperative, more ceasless, more inobviable than in women, except in the cases of seamstresses, factory workers, typewriters, etc. And a proof of this is this: In those countries, cities, etc., where women are more and more taking up the occupations of men, the suicide-rate of women is proportionally increasing. In no country is this so much the rule as in our own, and it is here that the proportion of women suicides is rapidly increasing. In 1905 the actual numbers were 6,556 men and 3,426 women, the male rate less than double, it should be noted, while in other countries the proportion is 1 to 3 or 4. More than five million women were earning money in 1900. The fact is highly significant.

As to the relative rates among the married and single and the divorced, the influence of venereal disease rises to modify but not wholly do away with the effect noted.

The Suicide-rate and the Time of Life.—But the most striking and convincing proof of the theory of the influence of the sequels of eyestrain in producing suicide pertains to the time of life at which the numbers of suicides increase, reach their acme, and decline. The following diagram, from the U. S. Statistical Report, Registration area, presents the matter succinctly:

NUMBER OF DEATHS AT EACH AGE PER 1,000 AT KNOWN AGES.

Age.	Ages. 1900. Males.	1900. Females.	1890. Males.	1890. Females.
Under 15 years	1.2	7.8	3.2	2.3
15 to 19 "	18.8	100.5	23.7	92.8
20 " 24 "	68.8	158.0	69.2	158.4
25 " 29 "	92.6	135.8	92.9	144.8
30 " 34 "	103.4	109.7	99.4	99.5
35 " 39 "	114.2	124.0	103.9	83.7
40 " 44 "	117.3	90.1	100.0	83.7
45 " 49 "	113.4	75.7	119.9	81.4
50 " 54 "	105.7	50.9	110.3	83.7
55 " 59 "	79.2	40.5	82.7	49.8
60 " 64 "	62.3	28.7	68.6	40.7
65 " 69 "	50.4	27.4	53.8	24.9
70 " 74 "	35.8	23.5	41.0	13.6
75 " 79 "	25.0	14.4	20.5	27.1
80 " 84 "	9.2	7.8	8.3	6.8
85 " 89 "	1.9	3.9	2.6	6.8
90 years and over	0.8	1.3	...	...

If one should see the table of the male rate only, or even that of the combined male and female rate, one would wonder at the peculiarity of this age incidence. What a deplorable fact that at the ripest period of life, when a human being is at his highest value, from 24 to 55, he should kill himself, and the heavy investment of the community in bringing him to maturation and possibility of usefulness should be lost. There is but one fact that can explain this. The terrible disproportionate increase in female suicides from 16 to 30 years, caused, in part, by love and shame, not only does not contradict the amazing line of the general curve from 20 to 50, but should put an end to another apparently deathless superstition which has afflicted humanity, even our profession, long past its time. According to a theory hoary with antiquity, the diseases of women have been supposed to be multiplied and intensified by the menopausal factor. Expert oculists have known for many years that this factor has little or nothing to do with the increase of bodily or mental disorders. Had the upholders of the superstition cast but a single glance at the foregoing table, the nonsense might have had an ending. It is presbyopia, with its doubling and trebling of eyestrain, which occasions the increased disease and suicide at the ages of from 40 to 60. For this glance would have shown the uniformity or lessening of the female rate at this time of life, while among men (unaffected with menopausal woes!) the rate is highest from 35 to 54. Another way to view the fact is that the average age at death in the registration area, from suicide, was 43.6 years in 1900, 44.1 in 1890. Turn where one will, the reproving of the truth is peculiarly striking. In England, 1871-1874, the proportions per 1,000 cases of suicide were as follows:

	Men.	*Women*
From 10 to 15 years	3.7	8.2
" 15 " 20 "	23.2	66.7
" 20 " 25 "	50.5	76.2
" 25 " 35 "	139.3	156.2
" 35 " 45 "	194.5	175.1
" 45 " 55 "	211.7	205.9
" 55 " 65 "	217.8	175.1
" 65 " 75 "	122.5	107.7
" 75 " 85 "	33.3	27.7
" 85 and upwards	3.5	0.6

It is thus incontestable that the ages at which suicide is committed, barring the rise, in part, from love and shame in young women, is accurately paralleled by the increase of eyestrain and its systemic sequels. The male rate shows the parallelism uninfluenced by the temporary factor especially present in young women. At the end of the presbyopic strain, at a little over 60, the eyestrain factor ends, and the steady contributing factors of lessening vitality, outlived life, failure of a dozen different kinds, find their proper function in the quickly lessening rate. The profound cause, the secret variant is the ocular function of accommodation, which, with almost unexceptionally present astigmatism, etc., is put to impossible tasks with the beginning of adult life, rises to doubled tragedy at about 30, and is quadrupled at the ages of from 40 to 60.

Suicide and School-pressure.—That the variant suicide rate in different countries and communities depends so largely upon the spinal, the cerebral and nervous and the nutritional diseases caused by eyestrain gets its final confirmation in the fact that suicide everywhere depends upon the school pressure or the educational compulsion. The greater the number of hours of study demanded of the school child and youth, the greater the number of suicides. The exact figures of all nations are impossible to obtain, but Hon. W. T. Harris of the U. S. Bureau of Education writes me that in the German-speaking countries (where the suicide-rate is highest) the rule in general is about 1,500 hours of schooling per annum. The average in U. S. schools is in the neighborhood of 1,000 hours. Bronc said that the number of suicides in a country could be calculated from the number of pupils in the public schools, and Morselli states that Saxony is the most advanced as to schools and education, and it is the focus of irradi-

ation of suicide in all central Europe. In the conscription of 1865-1873, 59 per cent. of the Italian conscripts could not read and write, 23 of the Belgian, and 3 of the Prussian. Mayo Smith says that "the connection of suicide with education is explained, of course, by the fact that mental development brings greater danger of nervous disorders and greater sensitiveness to mental and physical suffering." But does it? One may promptly answer, *no.* That is a clear case of begging the question; and moreover the explanation does not at all explain. It is at one stroke a *petitio principii* and a *lucus a non lucendo. Per se* intellectual development or "culture" has no connection with ill-health; of itself it is not a cause of "nervous disorders," or of "greater sensitiveness to mental and physical suffering." Something else that may or may not accompany the intellectual progress may cause these morbid products; if one looks about him he quickly sees that his intellectual and educated friends are no more prone to morbidity than those not so mentally progressive. It is a proverbial fact that great intellectual men have generally exceptionally long lives. A glance at any table of the relative incidence of suicide-mortality of the different occupations at once ends such a contention. The explanation of De Greef, that "the prevalence of suicide in the intellectual and liberal professions is due to a peculiar instability resulting from their specialty—a disturbance of equilibrium," again covers with words but does not explain. All such reasons miss the true reason that in general the amount of "near-work" with the eyes is the governing condition, and that certain eye-defects, especially astigmatism, ruins the health of the "educated," while in those without such optical defects there is freedom from suffering regardless of the intellectual or ocular work. Let us discriminate!

The increase of child-suicides in countries demanding the greatest number of school hours throws another lurid light on this aspect of the question. In Prussia the number of children committing suicide has steadily risen. In 1896 there were 2 cases under 10 years of age, 63 from 10 to 15, and 444 from 15 to 20—333 school boys and 176 girls, a total of 509. Failure in examinations or promotion, or fear of punishment, were the motives ascribed in the majority of cases. What a ghastly commentary! Again appears the disproof of the fallacy as to the supposed cause of mischief in menophania and love. There were 333 boys and 176 girls, under 20, who committed suicide. Hence even in the high suicide-rate of young women it is probable that eyestrain is a frequent cause, as it is in young men, rather than passion and shame. The common diseases of children generally caused by eyestrain, the forerunners and prophecies of coming tragedies, are night-terrors, nervousness, loss of appetite, anemia, vomiting, dyspepsia, headache, migraine, etc. The youth that shows an exceptional intellectual development does so by means of study and reading. In this way the truth that may be in Byron's "Whom the gods love die young," acquires a new and real, a medical significance.

Pleasure-seeking as a profession, the rage for luxury, "the pace we lead," "the strenuous life," have been vaguely and uncritically charged with vastly increasing the mortality, morbidity, and suicide-rates. There may be many reasons for discouraging and inveighing against these things, but there is little reason for believing that such customs much increase the number of suicides. The strenuous do not kill themselves, nor do the pleasure-seekers, those greedy of luxury and wealth. Other causes lie deeper and are more determining. Neither does the decline of religion suffice to solve the mysteries. Sir Thomas More came nearer the explanation when he justified suicide "if the disease is not incurable, but also full of pain, making life a torment." In Oriental countries the desire to escape disease and suffering is acknowledged to be the source of most of the suicides that occur.

The Causes of Suicide in the United States.—Take the not untrustworthy report of the *Chicago Tribune* (Dec. 31, 1905) as to the causes of the nearly 10,000 suicides in the United States in 1905: "Business losses" account for only 32; alcoholism for 375; love for 958, and domestic troubles for 1,525. No one can reasonably doubt that behind these namings not a small share would, by more exact knowledge, be found to have a better explanation in some form of physical or psychical ill-health. These cases would at least offset those in the rest of the classes which were not due to ill-health. There remain, then, these: Despondency, 4,134; "insanity," 1,826; ill health, 411; unknown, 721; total, 7,092; to be set over against the 2, 890 as probably and approximately not due to disease; that is, three times as many cases more or less certainly consequent upon ill health than upon all other causes combined. The enormous number that could be classifield as due to "despondency" is of amazing significance. One must remember that it is the mystery and painfulness of one's affliction that leads inevitably to despair. As a rule the lethal diseases are comparatively painless, and their nature is at least supposably understood. Moreover it is not those afflicted with the directly lethal diseases who commit suicide. It is those struck in the dark, as it were, and by an unknown fate, who despair. One could successfully show that in all history and religion the idea and belief in Fate and Fatalism is in fact the work of disease. Vertebral disease, sick headache, headache, bilious attacks, dyspepsias of many kinds, "neurasthenias," loss of will and vital force, nervous, cerebral, and psychic disorders, and inabilities to meet the demands of circumstance, these are the diseases which breed despondency; they are painful, they are incurable by most modern medicine, they are diabolically persistent and inexplainable by the popular or the accepted scientific theories. And yet in the vast majority of instances they are due to eyestrain. This is a truth too long unacknowledged, although known by a few wise men for a generation. It is not "hobby-riding" or "exaggeration," or a specialist's infatuation; it is sober truth, new truth, truth that is startling thousands of observant scientific minds, and which will soon revolutionize the philosophy and the practice of medicine, and of hygiene, personal and public. Let us be wary of obscuring the truth, or of postponing its acceptance by prejudice or by a cynical satisfaction with old and accepted theory.

Some Clinical Suggestions.—In monographs on suicide, individual cases are too rarely reported, but when it is done, such sentences are often met: "From dyspepsia," "excessive study," "feeling so miserable," "studying for examinations," "suffered such torments," "lack of self-control," "weakness and pain to an intolerable degree," "infirmity and illness is the cause of my suicide," "an old complaint of my eyes came once more upon me," "I was a draughtsman and my sight was useless to me," "a melancholiac," "want of sleep," "periodic attacks of severe headache," "brain fever," "mental irritability," "general health bad," "nervous irritability."

From my own newspaper cuttings of the past

few months I quote a brief word or two given as the causes of suicide: "In bad health," "suffered much from pains in the head," "thought he was losing his mind," "ill in bed for a long time," "return of melancholy," "because his wife had been ill so long," "ill a long time," "addicted to morphine to relieve suffering," "melancholy from excessive study," "incurable illness," "pain too great to be borne," "upset by overstudy," "had been in a sanitarium," "broke down while studying," "gastritis," "nervous collapse," "suffered from melancholia," "suffered from a nervous affection for two years," "threatened with blindness," "broken with illness," "depressed from lack of sleep while studying," "despondent from long illness," "ill health and consequent despondency," "in low spirits," "worried over her health," "not able to sleep," "sickness has driven me to this deed," "suffering from nervous breakdown," "melancholia," "ill health for several years," "another attack of melancholy," "despondent after illness." "despaired of regaining his health," "severe toothache," "despondency because of ill health," studying hard at night."

If one looks over the biographies of the literary and musical geniuses who have done vast amounts of ocular labor, he is at once struck by the fact that some had good health and worked with ease and happiness, while others much or most of the time were at intervals plunged into intense pain, and mental and physical misery. Goethe, Humboldt, Mommsen, Mozart, Ruskin, Kant, Liszt, Wordsworth, Macaulay, Emerson, Hume, Verdi, Gibbon, St. Beuve, Bronte, Meyerbeer, Scott, Calderon, Hawthorne, Dumas, Scribe—a hundred others, did vast amounts of ocular labor all their lives, and they had no headache, insomnia, biliousness, or melancholy. Not one of that class was a pessimist. But Maupassant, Carlyle, Huxley, George Eliot, Lewes, Wagner, Parkman, Spencer, Margaret Fuller, Nietzsche, Symonds, Taine, Berlioz, Balzac, Tschaikovsky, Flaubert, Swift, Heine, Leopardi, and so on—how was it with these? They were pitiful and terrible sufferers all their lives, they were usually atheists and pessimists, they had all the typical symptoms of eyestrain—"migraine," sick headache, insomnia, biliousness, vomiting, despondency, tiredness of life—whenever they used their eves; and they got immediate relief when they stopped near-use of their eyes, *i.e.* when they walked the hills or moors most of the day. DeQuincey, Mrs. Browning, and Flaubert saved some wreckage by means of opium; Parkman, Browning, Whittier, Darwin, and Spencer by renouncing most all eye-work. But the others found no such methods and suffered, and their work suffered, and the world suffered, in consequence., Darwin was always near to despair; Carlyle's life was much of it a shuddering at its uselessness, and he thought death advisable; George Eliot said that illness is the one woe for which there is no comfort—no compensation; she was ill all her life of sick headache—due to her eyes—and fought against despondency for forty years with heroic valor. Of Lewes the same could be said. Wagner was near to madness and suicide all his life because of his eyestrain. "For me there is no salvation but death." Parkman was afraid he really did have a strong constitution, and the riddle of his life is now solved; he was pronounced mad by great alienists, and was said to have "an inherited affection of the brain" by expert ignoramuses. A library of nonsensical writing, professional and unprofessional, need not have come into being if Mrs. Carlyle had had a scientific pair of spectacles. If Spencer could have read the necessary amount his "Synthetic Philosophy" would have lived much longer. "Neuralgia" and "neurasthenia" blasted Whittier's career. Margaret Fuller's tragedy was also of ocular origin.

Except Flaubert no man ever suffered more than Nietzsche, and the sole cause of his suffering was his eyes. He had the worst sort of "migraine," the worst eyes, the worst kind of life, and the worst philosophy it is possible to imagine. He lived with despair all his life, and ended his life in the insanity of cerebral paralysis produced by near use of his eyes. That Taine did not end as tragically is due perhaps to the fact that one of his eyes was excluded from function. Symonds, tormented by eyestrain, often thought of suicide, and at twenty-eight seriously contemplated it. The gloom and suffering fro meyestrain in the case of Berlioz was so great that suicide was many times planned, and twice attempted. Once emesis prevented death, and another time he was dragged from the water unconscious and saved from suffocation by the efforts of others. "Insane depression," "profound disillusion," utter hopelessness, even at the height of brilliant success, characterized the whole life of the great eyestrain sufferer, Tschaikovsky. Mason writes of him: "He says that had he remained a day longer in Moscow he should have drowned himself, and it is said that he did go so far, in his terrible depression, as to stand up to his chest in the river one frosty September night in the hope of literally catching his death of cold and getting rid of his troubles without scandal." One of the most perfect of pessimists, one of the greatest of all sufferers from eyestrain diseases, was Flaubert, and he speaks himself of "grazing madness or suicide," always wishing for death, etc.

Dr. Pronger of England writes: "How often patients [eyestrain patients] have told me they have been on the verge of suicide"; and he adds that "errors of refraction are responsible for a large proportion of the suicides occurring daily." Again he says, and truly, that "It is quite conceivable that suicide would be more likely to occur in those who had been for a long time enduring the mental torture resulting from the [ocular and other] conditions I have enumerated, and which had rendered life a burden." In my own practice I have had a number of patients who confessed that they had but barely missed suicide. Here are notes of three:

"Three months ago a professional student from a great university came to me with a typical history of intense eyestrain which had forced him twice to renounce his intended career. Utter breakdown was again upon him. The cerebral and psychic symptoms were terrible. Suicide was constantly in his mind. He returned recently to thank me for his glasses and to say he is happy and studying hard, and that he stands scornfully smiling at the locomotive as it approaches him, while he has not the least hint of his old impulse to throw himself before it."

"As I write this a patient comes in bright and happy and healthy, who two months ago was the absolute reverse of these things, and whose life had been made as miserable as that of Wagner, and from the same cause. In his melancholy and suffering his greatest danger had been suicide. Great nerve specialists had drugged him to stupor, or had 'rested' him nearly to death. Luckily he escaped the hydropathist and Christian Scientists."

The wife of a rich physician, living in the West, at the presbyopic age of forty-four, for several years had typical sick headache or "bilious attacks," clearly and demonstrably due to eyestrain. She would not wear glasses. In her agony she suddenly forgot home, children, and husband, and killed herself.

SHOCK.

By LUCY WAITE, A.B., M.D.,

CHICAGO.

HEAD SURGEON TO THE MARY THOMPSON HOSPITAL FOR WOMEN AND CHILDREN.

Shock in its widest significance covers the whole of medicine. From the slightest physical traumatism or the lightest mental depression to the most profound impressions on the vasomotor centers causing instantaneous death, the difference is only one of degree, the phenomena being the same. It would therefore be impossible in one short chapter to follow out the subject in all its various ramifications in the field of medicine and surgery, and it must suffice to treat it in a comprehensive manner as an affection primarily of the nervous system, with the secondary involvement of the vascular system as a whole.

While it is only during the last fifty years that any scientific experiments have been made with a view toward discovering the pathology of shock, as early as 1826 Travers, in his work on "Constitutional Irritation," gave an exact description of its phenomena. The first treatise on the subject that I have been able to find was published in 1868 by Edwin Morris, F.R.C.S. In this he states that the first mention of shock in medical literature was in 1819, in the works of Hennen and Guthrie, writing on military surgery. Morris considered death from shock due to functional disturbance of the brain, the heart being affected only secondarily. He placed no emphasis on the part played by the sympathetic system, and mentions this only once incidentally as the *par vagum*, and says it connects the spinal cord, brain, and heart. He treats of shock under two headings, surgical and shock from mental causes. He gives the classical symptoms and concludes that shock is due to paralysis of the nervous system destroying the normal function of the brain and withdrawing the nervous stimulus from the heart. He confuses shock and concussion of the brain, but warns against confusing this condition with extravasation in injuries to the brain. I have given a brief synopsis of his brochure because it is written in a comprehensive manner, and as it appeared as late as 1868, we may assume that it contains all that was known on the subject up to that date. Previous to this mention was made of the subject in Cooper's Medical Dictionary in 1838, and in Copeland's Dictionary in 1858. In Cooper's Surgical Dictionary, published in 1859, however, there is no mention of shock.

One of the most interesting landmarks in the history of the literature on shock is Davey's work, published in 1858. Under the heading of "Syncope" he gives a long dissertation on the phenomena of shock, although this word is used only once, and he foreshadows both the present theory of the pathology and the latest treatment as demonstrated by the experiments of Dr. George C. Crile and others in his observations on collapse after labor and the too rapid escape of the ascitic fluid in paracentesis abdominis. "I am, however, confident," he says, "that the *bona fide* explanation of the fact is to be sought for in loss of the long-accustomed adaptation or relationship between the containing and contained parts of the abdomen, whereby the ganglionic nervous system is at its very center more or less paralyzed." He says he has no doubt that the many cases of sudden death attributed to cerebral hemorrhage, disease of the heart, air embolism, etc., are in reality caused by "syncope" as he terms it, and that the cause is to be found in the fact that "the ganglionic nervous system has been drawn on so largely by the cerebrospinal and muscular systems that there is nothing remaining for the thoracic and abdominal viscera—no stimulus left for the vital organs. Mr. Paget, writing in 1862, gives the phenomena and treatment. Later Brown-Sequard and Savory (1870) made the valuable discovery of the pathology of shock. Brown-Sequard announced as the result of his work the theory of anemia of the cerebral centers due to a more or less persistent contraction of the capillaries through the vasomotor center. The experiments of Goltz on frogs were the most important work in this direction until the last few years. With Brown-Sequard and Savory he held to the theory of cardiac paralysis. He showed that through the inhibitory influence exerted upon the splanchnics, the abdominal vessels were suddenly dilated. In Quain's Medical Dictionary, 1884, is a statement of the status of the subject of shock at that date, which concludes: "For the present we may thus accept as the most plausible interpretation of the symptoms of shock a sudden dilatation of the abdominal vessels, attributable to an inhibitory influence exerted upon the splanchnics, through the medium of a special reflex center." Not much has been added to this explanation of the real pathology of shock, but valuable experiments have been made in recent years in the line of pathology, and some working toward a more rational treatment by George C. Crile, Robert Dawbarn, Harvey Cushing, Eugene Boise, Guy C. Kinnaman, John H. Packard, and others of our profession. In the extensive surgical encyclopedia edited by Dupley and Reclus in 1890 is the statement that it is only during the last twenty years that shock has been studied in France, and that the French in acknowledging the origin of the researches in this subject often use the English orthography, although having a legitimate word in their own language, *"choc."* A differential diagnosis is made between shock and syncope, and the article concludes by saying that in fact we know nothing of the pathological anatomy of shock or of its pathogenesis. The entire bibliography on shock is so meager that it may be interesting from an historical standpoint. In addition to those already mentioned, the field is practically covered by the authors included in the bibliography at the end of this article.

From clinical observation of the phenomena of shock a rather arbitrary division of the etiology has been made, viz., predisposing and exciting causes. To establish this as a scientific classification much more must be known regarding susceptibility to shock. Infants are said to be almost immune, while youth is considered the period of the highest susceptibility. Immunity is therefore before the age when the cerebrospinal and sympathetic systems assume their reciprocal positions in the nervous system, susceptibility from the time when the untrained cerebrospinal system assumes more established control over the sympathetic until the element of mental influence comes in as a factor. To counterbalance this extreme susceptibility of youth comes in the fact that at this time the resisting powers are greater and many cases are recorded by different authors of recovery from the most profound shock in the young which must certainly have proved fatal in the old. It would almost seem that the proposition could be laid down that the power to withstand and overcome shock is in inverse ratio to the susceptibility. Dr. Kiernan says that the insane are not susceptible to the influences which produce shock in the sane, and in fact the effects may be directly contrary; a wide field for study and speculation. Certain peoples are said to be practically immune and others to be little affected. Dr. John H. Packard writes interestingly on this subject. He says that Hindoos bear injuries

and operations impassively; that negroes are not easily affected, and that Americans are especially susceptible to the influence of shock. It has been observed that injuries inflicted while the subject is under the influence of intoxicating liquors rarely produce severe shock. If all these clinical observations can be substantiated it would point very strongly to a large mental element in every case of shock, either directly or indirectly. When all is said, however, the real factor in each constitution which speaks for or against susceptibility, the vital force, will, after all, no doubt, remain the unknown quantity. As regards the varying degrees of susceptibility in the different organs of the body, the most vascular tissues and those most highly supplied by the sympathetic nerve have been found to be most easily affected. In the present light of our knowledge we may consider as predisposing causes all conditions which impair the nutrition of the nervous system and consequently the circulation, exhausting diseases, prolonged physical pain or mental strain, insomnia, melancholia, in fact, everything which reduces vital force. Mummery says in his second Hunterian lecture that in elderly patients a very high blood pressure is generally observed, largely accounted for by arteriosclerosis, and that in such patients a relatively slight fall in blood pressure may produce shock. It is as a predisposing cause that hemorrhage plays its proper rôle through the secondary physiological phenomena of anemia, which leaves the ganglia to be bathed with impoverished blood and as a surgical condition to be handled surgically should be sharply differentiated from shock proper. The exciting causes of shock may be more satisfactorily considered under the classification of traumatic and mental. Direct traumatism of the tissues may result from accidental injuries or from trauma during the course of surgical procedures. Many writers treat this last condition under a separate classification as surgical shock. It seems true that this subject can be treated scientifically only as a subdivision of the general classification of traumatism, which is either accidental or surgical. The confusion has arisen by considering hemorrhage as an exciting cause of shock instead of giving it its proper classification as a surgical complication, and secondly by the involvement of the anesthesia in the etiology. All surgical writers agree that the frequency of shock has greatly lessened since the general use of anesthesia, and this fact speaks loudly against operating under partial or local anesthesia, as a routine practice. I have seen patients profoundly influenced by an excessive quantity of the anesthetic, on account either of the manner in which it was administered or of the length of time the patient has been held under its influence, with no symptoms of shock whatever, and I cannot think that the effects of long anesthesia, serious as they are, can legitimately be considered as factors in the production of shock. The whole story of a depressed nervous system following a prolonged anesthesia is told in the added traumatism caused by the repeated and unnecessary handling of the tissues and the exposure to atmospheric influences of tissues normally protected by the coverings of fascia and skin. During extensive experimentations in intestinal operations on dogs Dr. Byron Robinson demonstrated that the shock following these procedures was in direct proportion to the amount of manipulation or traction on the abdominal viscera and duration of exposure, that is, the amount of trauma inflicted upon the sympathetic nerve. Sudden blows, especially in the region of the solar plexus, burns and scalds involving large areas, all manner of traumatic injuries, especially those producing extensive crushing of tissues, are the principal exciting causes in shock from accidental traumatism. It has been observed that burns involving a large area causing extensive nerve periphery trauma give rise to more profound symptoms than deeper burns covering a small area. Irritation in one organ may produce nerve storms in a distant one. The introduction of the sound into the uterus or the catheter into the male urethra may produce faintness, nausea, or even vomiting. Dr. Nicholas Senn demonstrated a rare case in his clinic which well illustrates the principle of reflex nervous irritation. The patient came into the hospital with a history of anuria for sixty hours. The right kidney was enormously distended, the left apparently normal. A diagnosis was made of right ureteral calculus, which was removed. During the period of convalescence both kidneys secreted an equal amount of urine, proving conclusively that the suppression of urine from the left kidney was caused by the reflex irritation produced by the disturbance in the right. The size and extent of the renal ganglia and their nearness to the solar plexus give to the kidneys an especially strong sympathetic connection. From the first observations made on the subject to the present day, all writers have recognized the mental element in the etiology of the phenomena of shock. Davey, 1858, cites in detail many cases and says the part played by the mind in the production of "syncope" is not sufficiently appreciated. Clinical observation has established the fact that profound mental impression may cause all the nervous phenomena following a blow over the solar plexus. Sad news, fright, violent emotions may be followed by the same vasomotor paralysis with all its accompanying nervous manifestations; and when this is said, all has been said regarding our knowledge of the influence of the mind in the production of the phenomena of shock.

As the result of some experimentation and much speculation two theories regarding the pathology of shock have been proposed, viz., vasomotor paresis and cardiac paralysis. Almost all of the modern investigators hold to the theory of vasomotor paresis. The nervous impression is conveyed to the medulla by the afferent nerves, causing vasomotor paralysis and dilatation. There is a more or less rapid fall in blood pressure. The vessels lose their normal tonicity which is necessary to the rapid transition of the blood, the first effect is contraction in the caliber of the capillaries followed quickly by dilatation with at first increase in rapidity of the blood current, but in proportion as the dilatation increases the rapidity decreases and may proceed to a complete stasis. The right side of the heart becomes engorged and does not empty at each contraction, blood accumulating largely in the relaxed veins and leaving the arteries partially emptied so that the patient bleeds into his own veins. The blood is poured into the abdominal vessels. Cerebral anemia results as a natural consequence and a slowing of the activity of all the different viscera dependent for the fulfillment of their physiological functions upon a perfect blood supply. The influence on the heart together with all other viscera is therefore secondary to the paralysis of the vasomotor system through the great reorganizing center, the solar plexus, the abdominal brain. The phenomena of shock are therefore the result of a reflex inhibition affecting all the functions of the nervous system, causing a lowering of the general blood pressure; checking normal metabolism, arresting the ex-

changes between blood and tissues; the venous blood becomes red, temperature falls in consequence of the lowered blood pressure, respiration slows, and we have a picture of systematic asphyxia. The entire mechanism of life is deranged, the balance of power is destroyed, and each organ is in independent control of its own functions for the time being and consequently only as long and as thoroughly as its limited reserve force will allow. Brown-Sequard, Goltz, and Savory advanced the theory of cardiac paralysis. They gave as the conclusion of all their experiments that shock was caused by a violent impression on some portion of the nervous system acting at once through a nerve center upon the heart and destroying its action. No reliable findings have been discovered at autopsy. Parascandala claims to have found certain changes in the spinal cord after profound shock affecting the cell body, prolongations in the nucleus and nucleolus, consisting of chromatolysis and fragmentation, nuclear and perinuclear.

It must be admitted that the pathology of shock after all remains very indefinite and unsatisfactory, the *x*, as Dr. Senn has called it in the surgical formula. It is therefore very difficult to give a comprehensive definition of this *ignis fatuus* in the domain of pathology. Based in reality more on the phenomena than upon the pathology, according to our present light we must consider it as primarily a disturbance of the great sympathetic nervous system affecting secondarily the entire vascular system, a more or less profound impression on the sympathetic nerve producing a vasomotor paresis with the consequent dilatation of the right side of the heart and the large vessels, especially the abdominal ones, and in consequence lowering the general blood pressure and deranging through the solar plexus all the automatic visceral ganglia, and consequently destroying their functional activity, rhythm, absorption, and secretion.

The phenomena of shock manifest themselves through the tripod of vital forces, the nervous, circulatory, and respiratory systems, and principally in those organs most highly supplied by the sympathetic system. The rhythm of the viscera is disturbed, secretions are diminished, causing an intense thirst, which is the cry of the tissues for fluids; there is a general trophic disturbance; the heart action and the respirations are increased, the temperature is subnormal, the face is pale, the lips are blue, the pupils are dilated; there is nausea with vomiting and restlessness, more or less pronounced according to the degree of shock, until the stage of collapse, when the reflexes are lost. A cold, clammy sweat appears on the entire surface of the body, and the extremities are cold. Shallow respirations with frequent sighing, yawning, and hiccoughs are often added to the clinical picture. In the most profound shock, in which the cerebrospinal system is involved, this picture may be changed by the substitution for the phenomena caused by a hyperirritation of the sympathetic system—nausea, vomiting, and restlessness—of manifestations resulting from a secondary depression of the cerebrospinal system, causing a loss of reflexes, as involuntary urination and bowel movements; delirium and even stupor may appear. The cold sweat, rapid, irregular pulse, and subnormal temperature here persist in a more profound degree, some observers having noted a fall in temperature of 6° F. During the War of the Commune observations were taken in regard to the temperature after injuries. The average temperature varied from 96.5° to 97.5°, the lowest registering at 93.5°. The fall was greater after shell wounds and the curious fact was noted that there was a uniform lower temperature among the insurgents than among the regular troops. Authenticated cases have been reported in which jaundice, deafness, and arrest of lacteal and menstrual secretions have followed profound shock. Many attempts have been made to establish a classification of the phenomena of shock, but all are unsatisfactory for the reason that one state runs so insensibly into another that it is impossible to measure the degree except by the rate of recovery, and here again comes in the unsolved problem of susceptibility and resistance and we simply travel in a circle. The only classification which is any aid in diagnosis and prognosis is a differentiation between the state implicating only the functional activity of the sympathetic system and that in which the cerebrospinal system is also involved, and even here the symptoms run so imperceptibly into each other that classification is elusive; even in collapse, consciousness may be retained until death.

The intensity of physical shock is influenced by four principal considerations: the extent of the injury, that is, the number of nerve peripheries involved, the nearness of the traumatism to the solar plexus; the character of the injury, the more crushing or bruising of the nerves the greater being the nervous impression; and the severity of the pain produced. It is therefore from the standpoint of intensity rather than by means of a scientific classification that we must study the phenomena of shock.

The diagnosis of shock is simply the recognition of the clinical phenomena, as here we have no chemical or pathological findings to aid us. The clinical manifestations of this nerve storm are, however, so pronounced that practically the only difficulty lies in differentiating this condition from syncope caused by severe hemorrhage with which there is danger of confounding it. When syncope coexists with shock it is often extremely difficult to establish the presence of internal hemorrhage as a complication. In one condition the blood leaves the peripheries and congests the abdominal vessels, in the other the large and small vessels are equally deprived of the usual volume of blood. In nervous shock certain tissues only lose their blood supply, while there is no diminution in the quantity of blood. In the one the primary violence is to the nervous system, in the other the circulatory system is attacked directly. Syncope, causing always a cerebral anemia, is practically identical with the last manifestations of overwhelming shock or collapse. As a recognition of the presence of hemorrhage is often of the utmost importance, sometimes meaning even the saving of a life, we should never rest content with a diagnosis of shock until we have excluded the possibility of hemorrhage by every means in our power. If the patient is seen immediately after the injury, or in surgical cases in which internal hemorrhage may arise, the most reliable course for establishing a differential diagnosis is by observation of the pulse and temperature. Both conditions, to be sure, produce a rapid pulse with normal or subnormal temperature, but there is a decided difference in the course of the pulse and temperature which, with careful observation, one cannot fail to recognize. In internal hemorrhage there is a *gradually* rising pulse, more or less rapid according to the rapidity of the bleeding with a *gradual lowering of temperature,* the golden rule in abdominal surgery establishing the presence of internal hemorrhage laid down by Mr. Lawson Tait over twenty years ago. In shock proper, however, we have the maximum rapidity of pulse and depression of temperature at

the time of infliction of the trauma and coexistent with all other clinical manifestations, as the rapid shallow breathing, cold sweat, and dilated pupils. To illustrate: A patient is taken from the operating table with a rectal temperature of 99°-100°, pulse, 90-100. In half an hour the pulse is 110-120, the temperature is found to be 98°; in another fifteen minutes to half an hour the pulse has risen to 130-140 and the temperature is falling towards 97° and the diagnosis of internal hemorrhage is practically established. This rising of the pulse with a corresponding depression of temperature may be extremely gradual and extend over hours and even days in cases of slow bleeding, sometimes a mere oozing, as where a hematoma or a hematocele is forming, and before the period of infection or localized peritonitis, and here, of course, the diagnosis is more obscure but fortunately less urgent. If, however, the patient is taken from the table with a pulse of 120-140 or upwards, rectal temperature 98°-99°, respirations 30-40, and even if these conditions persist several hours, we have no reason to fear internal hemorrhage, and if after the first half hour of the patient's rest in bed the pulse and respiration slow ever so little and the temperature rise even a fraction of a degree, we may know that we have to deal with a case of recovering shock. The surgical nurse should be taught to make this differential diagnosis through a clinical study of pulse, temperature, and respiration, as it is to her that we must look for the accurate observation and prompt report of a condition in which minutes count in the saving of a life.

We have little to guide us in forming a prognosis, as here again the unknown quantity, the vital force of the individual, the power of resistance of the tissues to the nervous impression comes in as the most important factor in the equation. In general the temperature is the best guide here also. A persistence of 96° or below for several hours warrants an unfavorable prognosis, while even a slight rise from time to time may be taken as a happy omen.

The many and diverse theories regarding the treatment of shock show conclusively the chaotic state of the professional mind regarding this condition. One writer is so confused in his interpretation of the phenomena that he advised at the same time morphine, strychnine, digitalis, nitroglycerin, whiskey, and citrate of caffeine. No one has done more to bring order out of this chaos than Dr. Geo. C. Crile of Cleveland by his experiments on dogs. He has practically demonstrated not only the uselessness but the harmfulness of strychnine in shock, and that the rational treatment lies in raising the blood pressure. He lays down the principle that the treatment must be sedative to the sympathetic system and relaxing to the arterioles. To this end he advises compression of the abdomen and extremities to prevent the accumulation of blood in the large veins, with the administration of adrenalin given with salt solution. Dr. Halstead advises morphine, also normal salt solution. It is interesting to note that Morris, as early as 1868, advised opium, ½ grain every two hours.

If rest and heat, preferably moist, are added to these remedial agents, we have certainly fulfilled the requirements for treatment in accordance with all that is known of the pathology of shock, to quiet the nervous system and relax the arterioles. The addition of strychnine, digitalis, nitroglycerin, and whiskey is certainly irrational. The heart is already overworked by Nature's effort to repair the damage, and strychnine may prove to be what the whip is to the spirited horse at the end of the race, and under its influence the heart may exhaust itself in a last effort. When there has been hemorrhage as a complication, the first indication is most assuredly to restore the volume of blood, but it is certainly irrational to increase the quantity of blood suddenly when the normal amount is present in the vascular system and the difficulty lies in reality in properly caring for the usual quantity. It would seem theoretically that increasing the volume of blood rapidly under these conditions would only increase the local congestion in the large blood-vessels and make the ultimate restoration of the normal blood pressure more difficult. Small quantities of hot water per mouth or rectum sufficient to allay the thirst, or the slow, continuous rectal irrigation which introduces the fluid gradually and as the tissues are prepared to appropriate, seems to me to be more rational than intravenous infusion of a large quantity of fluid. Briefly stated, the treatment in hemorrhage is to restore immediately the normal volume of blood; in shock to restore the normal blood pressure. Dr. Robert Dawbarn calls attention to the danger of using plain water in intravenous infusion in hemorrhage, and says that experiments on dogs have proven that it will kill almost as quickly as prussic acid. He advises normal salt solution at a temperature of 118-120° F., one to two quarts, ten minutes to be taken in introducing it. If the kidneys are not functionating normally, the quantity must be lessened. Some writers make a point on the value of force of gravity and advise lowering of the head. Mummery says that the ideal treatment of shock would be the raising of the external pressure, and thus substituting an artificial peripheral resistance for the lost peripheral resistance caused by the exhaustion of the vasomotor centers, but that as yet this method is not practical. The administration of foods and drugs by the stomach is distinctly counterindicated. The same principle holds good here as in the case of the heart. The stomach is exhausted and oversensitive and should not be irritated or stimulated to work until the period of exhaustion has passed. Perhaps the principal factor in the therapeutics of shock is rest, anatomical and physiological rest. This, of course, forbids all stimulants, alcoholic as well as stimulating drugs. Light and sound should be excluded, that the tired brain may share in the general calm with which we seek to surround our patient.

The preventive treatment of shock lies almost entirely in the domain of surgery. Here is indeed the ounce of prevention worth a pound of cure. Paget, in 1868, advised hypodermic injections of morphine after operation, before the patient is restored to consciousness, to lessen the shock caused by pain. Davey, in 1858, recommended waiting in cases of shock injuries not complicated with hemorrhage until some of the "Promethian fire" had returned to the shocked tissues. Dr. Harvey Cushing and Dr. Crile advise the cocainization of main nerve trunks, thus "blocking" the nerves proximal to the site of operation, in severe cases in which shock may be anticipated. Dr. Crile has invented a pneumatic rubber suit with which he envelops the patient, which he claims assists greatly in maintaining the normal blood pressure. There is no doubt that much can be done by the proper preparation of the patient before coming to the operating table to prevent subsequent shock, and the practice of some surgeons, of rushing nonemergency cases under the knife without any preparatory treatment, cannot be too strongly condemned. It is self-evident that the more normal the condition of the system the greater

will be the resistance to shock. The indication then is to bring all organs as far as possible to their highest function. This is especially important in the case of the kidneys, bowels, and skin, the great eliminatory organs; these must actually secrete normally at the time of operation if we are to expect normal conditions to follow. Free drainage by means of nature's own remedy, water used liberally, internally and externally, for several days previous to operation will, in ordinary cases, be sufficient to put the kidneys and skin in good condition. A free catharsis, making sure that the entire intestinal tract is cleared, is of the utmost importance. The liberal use of normal salt solution as long before the operation as possible not only aids in the systemic drainage but increases the volume of the blood and promotes the rapid metabolism which is so important in preserving the quality of the blood. The stomach should be absolutely empty when the patient is brought to the operating table, as it is one of the first viscera to manifest reflex irritation and persistent nausea and vomiting keeps the patient in constant distress and the muscular system in action, preventing the rest and relaxation so necessary to recovery. Rapid operating, as rapid as is consistent with a proper attention to detail, is unquestionably one of the greatest factors in the prevention of surgical shock. The entire régime of the operating room should be conducive to this end. Every detail should be attended to as far as possible before the patient is placed under the anesthetic. Minutes wasted for any reason while the patient is under abnormal conditions are an injustice to all concerned. In abdominal surgery involving the peritoneal cavity there is little doubt that shock is in almost direct proportion to the amount of handling and exposure of the intestines. Mummery says that turning the intestines out of the abdomen is always followed by a sudden and dangerous fall of blood pressure. Methods of operating, therefore, in which these viscera are little or not at all exposed can certainly claim to be a factor in the preventive treatment of shock. I have frequently seen patients put to bed after the removal of large myomata (hysterectomy) per vaginam with no more symptoms of shock than after a normal labor. The choice of anesthetic in cases in which shock is apprehended is considered by some of great importance. Mummery says that ether anesthesia almost always causes a rise in blood pressure, while chloroform is usually accompanied by a fall in blood pressure; and he believes the chloroform-ether mixture to be the best anesthetic from the point of view of subsequent shock. It would seem, however, that there are more important points to be considered in the choice of an anesthetic, as the organic condition of the heart, kidneys, and lungs, as we have more definite knowledge of the action of ether and chloroform on these organs. The temperature of the operating room is of great importance and should be kept between 80 and 85° F. Wetting and chilling of the body should be avoided, and heat applied directly by means of a water cushion placed over the operating table assists greatly in preserving the normal body temperature. The mental state in which the patient comes to the operating table is, no doubt, here an important factor. Every effort should be made, therefore, to inspire the patient with confidence in the success of the operation, that the demon of fear may be exorcised from the sick room, that the spirit of hope may hover around the last few conscious breaths, and be the first to greet the awakening mind struggling back to consciousness.

PLEURISY WITH EFFUSION AND PULMONARY TUBERCULOSIS, WITH CASES OBSERVED AT THE HARTFORD HOSPITAL.

By HENRY FARNUM STOLL, M.D.,

HARTFORD, CONN.

[illegible] PHYSICIAN TO THE HARTFORD HOSPITAL AND THE WILDWOOD SANATORIUM; PHYSICIAN TO THE LINE FOR PULMONARY TUBERCULOSIS, HARTFORD DISPENSARY.

All who have studied the histories of tuberculous patients realize that there is an intimate relationship between pleurisy and tuberculosis of the lungs. Von Ruck[1] found that 22 per cent. of 1,000 cases were preceded by a pleurisy, but he considers that percentage too low in view of the number who have undoubted signs of pleuritis, yet give no history of pain or discomfort. Then, too, the subsequent histories of the cases of "idiopathic" pleurisy show that from 30 to 50 per cent. eventually die of tuberculosis, and we may presume that a considerable number become tuberculous yet die from other causes.

To explain this we may consider: (1) That their association is purely coincidental; (2) that the pleuritis paves the way for subsequent tuberculous infection by creating a point of lowered resistance; (3) we may assume that the pleurisy is caused by the tubercle bacillus. The first proposition we can reject as being untenable in view of the frequency with which the two conditions are associated. The proposition that the pleurisy predisposed to tuberculous infection cannot be as summarily dismissed. It is known that tubercle bacilli can pass through the wall of an alveolus and thence be carried by the lymphatics to the bronchial glands. In this way a bacillus may escape from a superficial alveolus and be carried along by the lymphatics ramifying on the surface of the lung, until arrested by a spot of pleura which at some previous time had been the site of an inflammatory process. Or a bronchial or mediastinal lymph node, already tuberculous, may, as the result of trauma or some acute illness, have its capsule ruptured or so weakened that the bacilli escape into the pleural sac. If the pleura is already the seat of pathological changes, the conditions are especially favorable for the development of a tuberculous lesion.

It is the third proposition, however, that has the greatest number of supporters, viz., that the pleurisy

is an evidence of tuberculous infection. Koch[2] obtained a tuberculin reaction in 72.3 per cent. of his cases, and Netter[3] found that 87 per cent. gave a positive reaction to tuberculin. By inoscopy (digesting and examining the coagulum) Jousset[4] found tubercle bacilli in a number of "idiopathic" cases, and others have demonstrated the bacilli by this method in fluid which gave negative results when injected into guinea pigs. According to Eichhorst's[21] inoculation researches two-thirds of all serous pleurisies are tuberculous. Cornet[5] considers primary tuberculosis of the pleura to be rare. He believes it is usually secondary to a superficial lung involvement, or to a tuberculous lymph gland. Hodenpyl,[6] on the other hand, believes primary miliary tuberculosis of the pleura is much more common than generally supposed, and that recovery occurs as a rule. He found evidences of a healed pleural lesion in nearly 50 per cent. of ninety-one adults who were free from other evidences of tuberculosis. Grober[7] showed that when the lymphatics are obstructed the current of the lymph is often reversed, so that afferent vessels become efferent. Thus he demonstrated that swollen tuberculous glands of the neck may obstruct the lymph and cause it to flow backwards, not infrequently carrying tubercle bacilli from the diseased gland down to the pleura. Recently Calmette,[9] who believes in tuberculosis by ingestion rather than by inhalation, has shown that involvement of the tracheobronchial glands may be secondary to a tuberculous infection of the mesenteric nodes, even though the latter seem free from disease. He and his coworkers found that the inoculation of animals with the mesenteric glands of children having tuberculosis of the tracheobronchial lymph nodes, always revealed the presence of tubercle bacilli in the mesenteric glands even though the latter appeared sound. Moreover they demonstrated that when small doses of bovine tubercle bacilli were fed to calves and kids the tracheobronchial and retropharyngeal glands eventually became enlarged, with or without lung involvement. The mesenteric glands which seemed normal were found by inoculation to contain tubercle bacilli. They also found by inoculation tubercle bacilli in the mesenteric glands of three children who gave no evidence of tuberculosis clinically. These latter findings are in accord with those of Rosenberger,[20] who demonstrated by inoculation that six out of fourteen cases (40 per cent.) who were free from any gross lesion of tuberculosis, had a tuberculous process in the mesenteric glands.

It remained for Widal[8] and Ravaut in 1900 to furnish us with a means of determining which of the pleurisies with effusion were tuberculous, and which were not. While subsequent investigation modified somewhat their original contention, yet their statement has been found correct, that a predominance of lymphocytes in an effusion speaks for a tuberculous process. Naunyn,[9] in 1903, observed that lymphocytes may also predominate in transudates, in long-standing infections, towards the end of an acute infection which is subsiding, or where the infection has been a mild one from its incipiency. The polymorphonuclear cells which generally predominate in an acute infection, have occasionally been found most numerous in the early days of a very acute tuberculous pleuritis, and sometimes in old tuberculous effusions, with demonstrable lung involvement. In the latter case, however, they are usually the forerunners of an empyema. Attention was drawn by Runberg[10] in 1897 to the difference in the amount of albumin in transudates and inflammatory effusions. In the determination of the specific gravity and the estimation of the amount of albumin we have a means of differentiating between transudates and tuberculous effusions, both of which show a predominance of lymphocytes. Carter[11] has shown that the cytological examination of the fluid is but one part of a complete examination.

The cases here reported were patients in the Hartford Hospital, and I am indebted for permission to publish them to the several attending physicians and surgeons on whose service they were admitted, and to Dr. W. R. Steiner, the attending pathologist, under whose direction much of the work was done. I have divided the cases into four classes. 1. Cases known to be tuberculous. 2. "Idiopathic." 3. Mechanical—Transudates occurring with kidney and heart disease. 4. Acute infections. It is fortunate that in several cases aspiration was performed more than once, as it demonstrates certain variations that may be met with, yet shows the uniformity of the results in general.

Class I.—*Cases known to be tuberculous.*

Case I.—Joseph B., age thirty-seven years, admitted August 12, 1904. Two sisters died of tuberculosis. Personal history: Had pleurisy five years ago; eight months ago caught cold, with dry cough. Since then night sweats, anorexia and loss of weight. Six days ago he became short of breath suddenly, and since has frequently been in fear of impending death. Pleural cavity was aspirated four times in nineteen days and over 4,000 c.c. in all obtained. Immediately after last aspiration adrenlin chloride (1-1000) 3i was injected into pleural sac, as suggested by Barr,[12] and there was no recurrence of the fluid while he was under observation, which was a period of four weeks. There were tubercle bacilli in the sputum.

Our experience demonstrated the advisability of giving a hypodermic injection of nitroglycerin gr. 1-50 when the adrenalin was used, which dose was repeated in case there was a sharp rise of blood pressure. When this was not done the heart action became very forcible, rapid and irregular in force and rhythm, the face anxious and drawn, and the mental condition one of great anxiety. Barr reported similar symptoms in one case in which he injected into the pericardial sac, but he did not observe it when the pleural sac was injected. The rapidity of absorption must vary in different cases. There were no unpleasant effects when the nitroglycerin was used in conjunction with the adrenalin.

Case II.—Agnes A., age twenty-three years, admitted October 2, 1905. Family history: negative. Personal history: Began coughing ten months ago. Five months later had "malaria" and night sweats. Has failed in strength. Lung extensively infiltrated; tubercle bacilli in sputum. Less than one ounce was aspirated.

Case III.—Samuel S., age twenty-nine years, admitted March 28, 1906. Father died of tuberculosis at age of thirty-six years. Personal history: Negative until three weeks ago, when he had a pain in the left side, and through upper part of left lung. Hard dry cough developed; 1,200 c.c. of blood-stained fluid removed from left pleural sac. Lungs seemed free from involvement, yet tubercle bacilli were found in the sputum.

Case IV.—John K., age thirty-three years, admitted March 5, 1905. Family history: negative. Personal history: Never been ill; never associated with a consumptive. About two weeks ago noticed a slight dry cough. The day of admission to the hospital, while in state of intoxication, was struck on the left side by a trolley car and knocked down.

He experienced severe pain in the side. Physical examination: All superficial lymph glands enlarged; heart negative; lungs, dullness merging into flatness from the sixth rib downward on the left side in mid-axillary line with diminution of breath sounds; abdomen, tense and tympanic with marked tenderness on left side. Two days later slight amount of blood in the vomitus and in the urine. Ten days later an area of consolidation was noted in the lower right lobe posteriorily; an effusion followed; temperature, 102°; pulse, 90. March 12 (one week after admission) leucocytes were 11,000 and on the 16th were 18,500. He was twice aspirated and each time tubercle bacilli were found in the fluid.

Class II.—*"Idiopathic."*

Case V.—Thomas S., age thirty-two years, admitted May 28, 1904. Family history negative. Had malaria eight years ago; three months ago he lived and slept with a man who had tuberculosis. He had been in good health until three days before admission, when he had a dull frontal headache, complete anorexia, nausea, prostration, and constipation, which symptoms have continued. Typhoid fever had been diagnosed by his physician. He had the usual signs of fluid in the left pleural cavity. Leucocytes were 8,200 and some days later 13,900. May 30, 720 c.c. were aspirated; two days later 450 c.c. were obtained, and at the end of a week 420 c.c. more were withdrawn. After the last paracentesis adrenalin chloride 3i was injected into pleural sac and the fluid did not recur. The lung did not appear to be involved.

Case VI.—Charles H., age sixty-one years, admitted July 19, 1904. His mother died of tuberculosis. Workman next to him in the shop continually coughs and expectorates on the floor. In good health until one month ago, when he felt pain in the left side of the chest. It slowly extended to right side as well, and since has had a sense of oppression in the precordium and shooting pains down the left side. For the past two weeks has had a cough. On day of admission 120 c.c. amber fluid were aspirated and 1,500 c.c. were obtained on the 25th. Leucocytes, 8,100. Gave positive reaction to 3 mg. of tuberculin.

Case VII.—Giovanni M., age twenty-three years, admitted February 26, 1906. Family and past history negative. Works in factory where he perspires freely and is often exposed to sudden changes of temperature. A few days ago while in perspiration he went outdoors and caught cold. Since has had slight cough and been feverish; no other symptoms whatever. Right pleural cavity aspirated and 720 c.c. obtained; no tubercle bacilli in sputum. For five weeks his temperature ranged between 104° and 100°, with pulse of about 110.

Case VIII.—Joseph M., age thirty-nine years, admitted October 15, 1904. One brother died of tuberculosis and another one has it at present. Personal history: Typhoid six years ago; about three weeks ago noticed a few sharp pains in the left side and complained of a feeling of malaise. Ten days ago felt a "tightness of chest" and began to cough. He tires rather easily, has had night sweats, anorexia and one chill. He had lost weight. (Eighteen months later there were tubercle bacilli in his sputum.) October 16, 960 c.c were aspirated and

October 30, 660 c.c. were obtained from the pleural cavity. Temperature, 102-103°; pulse, 90, slowly reaching normal.

Case IX.—Carrie B., age nineteen years, admitted January 11, 1905. A sister died of tuberculosis six years ago. Patient lived with her, but did not share same bed. Previous history negative. Eleven days before admission attempted to produce an abortion with a crochet needle. The day following repeated the attempt twice. The next day fetus and afterbirth were expelled. Four days later began to have fever, considerable foul smelling vaginal discharge and occasional chills. After the first few days in the hospital the vaginal discharge grew materially less, and the local condition seemed hardly to account for her temperature. A week after admission it was observed that fluid was collecting in the right pleural sac, and January 26, 620 c.c. of blood-tinged serum were aspirated. Eight days later, as fluid had recurred, she was again aspirated and 360 c.c. of amber-colored fluid were obtained. She had a cough with greenish expectoration and had several night sweats, not associated with a chill. No tubercle bacilli found in sputum. Temperature, which on admission was 104°, pulse 102, reached normal by lysis. When discharged, one month after admission, there was, in addition to evidences of a tuberculous effusion were it not for the low gravity. At the autopsy the pleura was found to be normal.

Class IV.—*Acute infections.*

Case XIII.—William M., age fifty-three years, admitted June 20, 1905. Father died of tuberculosis thirty years ago. Patient was at home at the time. A brother died of the same disease nine years ago and lived with the patient for the three weeks preceding his death. A grandmother died of "tuberculosis and asthma." Has always been well except for rheumatism twelve years ago and pneumonia six years ago, from which he recovered in a few weeks. He was brought to the hospital as the result of a stab wound of the left side, above the sixth rib and eight and one-half inches from midsternal line. The pleura was apparently intact, as there was neither pneumothorax nor subcutaneous emphysema. The lungs were clear. The wound healed readily, there being apparently no infection. June 26, six days after admission, a friction rub was heard above the sixth rib, left side. A pneumonia developed and an effusion followed; 140 c.c. of bloody fluid were aspirated, in which the polynuclear cells were found to predominate. Temperature, 103°; pulse, 100. He made an uneventful recovery, and nine months after discharge was in excellent health and his lungs appeared to be sound.

	CLASS III. MECHANICAL—TRANSUDATES.						CLASS IV. ACUTE INFECTION.
	Case X.			Case XI.	Case XII.		Case XIII.
Date	June 8, '04	June 23, '04	July 6, '04	June 2, '04	June 28, '04	July 2, '04.	Jan. 26, '05.

thickened pleura over right lower lobe, slight dullness, increased voice and whisper, and râles at the right apex. After leaving the hospital she lived out of doors for several months and gained in flesh and strength. In the fall of 1905 she had a slight dry morning cough for a few days. Otherwise in excellent health. Fourteen months after her discharge from the hospital I examined her in my office and found slight dullness above and below the right clavicle at the end of deep inspiration, and distant breath sounds at the right apex. Over the lower half of the right lower lobe were dullness and many dry râles, which were heard both posteriorly and laterally. Her temperature (3 P.M.) was 100°; pulse, 92.

The histories of the cases in Class III.—transudates—are omitted, as they are not especially noteworthy. Case XI was very edematous when admitted and had a right hydrothorax. He developed a pneumonia of the left upper lobe in a few days and had a leucocytosis of 51,000. The low specific gravity and the small amount of albumin stamped the fluid, which was subsequently withdrawn, as a transudate even though the polynuclears suggested an acute effusion.

In Case XII the large amount of albumin and the predominance of lymphocytes would indicate a

Several of these cases are deserving of more than passing notice. Case IV had never been exposed to consumption to the best of his knowledge, nor could any history of previous tuberculous infection be obtained other than a slight cough for two weeks previous to admission. He received a severe injury which caused, among other things, a pleuritis with effusion that not only showed the characteristics of a tuberculous effusion, but contained tubercle bacilli. Evidently he had an infected lymph gland, either bronchial or mediastinal, which ruptured when he was injured. Lymph glands harboring tubercle bacilli are not uncommon. Loomis[13] demonstrated that the bronchial lymph nodes in eight out of thirty adults apparently free from tuberculosis, contained tubercle bacilli, and Northrup[14] found that in eighty-eight of ninety-one cases of tuberculosis the primary focus was in a bronchial gland. Thus we see that tubercle bacilli may remain locked up, as it were, in some lymph gland, for a greater or less period of time, until some trauma or an acute illness acting as a turnkey, liberates them to their work of destruction.

One of Musgrave's[15] cases was caused by trauma, and though it showed the characteristics of a tuberculous effusion, he classified it with the "mild infections" of Naunyn, as there was no history indica-

tive of tuberculosis. In view of the number of cases reported where trauma appears to have been the determining cause of tuberculosis, it would seem that one is hardly justified in excluding it because of the absence of the usual symptoms. Netter[16] believes that 68 per cent. of the cases attributed to trauma are due to tuberculosis. Recently I saw a woman who had been in good health up to six months ago, when she fell downstairs and struck on her head. Since then she complained of pains of increasing severity in the back of the head. Examination of the spinal fluid showed tubercle bacilli.

The following case, not included in this series because of incomplete data, is nevertheless of interest in this connection from its clinical aspect alone. Belle E., age fifty-four years, was admitted to the Hartford Hospital September 15, 1904. Her husband died of tuberculosis. Twenty years ago she was ill for four months with "malaria." Since she has enjoyed good health and worked hard for a living. The day of admission she fell down an elevator shaft, sustaining a scalp wound, a laceration of the right thumb, and a fracture of the left scapula. On admission the lungs appeared to be negative. October 18, almost a month later, a friction rub was detected over the left sixth and seventh interspaces. An effusion formed, and on October 21, 1,020 c.c. of reddish serum were aspirated. The fluid was not examined. She remained in the hospital nearly three months, having a little cough, and during the last month profuse sweats nearly every night, which were only partially controlled by belladonna. When discharged there were a few fine râles over both lower lobes posteriorly, and in addition dullness and faint breath sounds over the left one. Temperature, 100-101°; pulse, 100; laterally was normal. In view of the late appearance of the fluid (one month after injury), its sanguinous color, and the development of profuse night sweats a month later, we may consider this as being in all probability a tuberculous (traumatic) pleurisy.

Case III appears to have been in his usual health until three weeks before admission, when he had a pain in his side, and a cough, yet tubercle bacilli were found in the sputum. Case VI had no symptoms referable to his pleura, and was thought to have typhoid fever. In Case VIII there was no history of exposure to consumption nor any previous sickness. He merely "caught cold," yet the subsequent course of his illness as well as the examination of the fluid left no room for doubt concerning the diagnosis.

Case X seems to be the most interesting and at first glance would appear to belong to the class of acute infections (mild type). An abortion, followed in four days by an infection, and at the end of two weeks by a pleurisy. From a superficial observation it would seem that the pleurisy was secondary to the infection of the endometrium. But the picture changes as we carefully analyze it. Not until the uterine condition was materially improved, and two weeks from the onset of the illness, did the pleurisy develop. Following the first aspiration the fluid recurred, necessitating a second tapping. She had a cough with greenish expectoration and night sweats, and at the end of a month had evidences of slight activity at the right apex, and a thickened pleura over the base. Fourteen months later she had an afternoon temperature of 100° and a pulse of 92, signs of a healed lesion at the right apex and a "smoldering" one in the lower lobe.

In Classes I and II the tuberculous effusions, the average specific gravity of sixteen examinations was 1,020, the lowest being 1,015, and the highest 1,028. They were characterized by a considerable amount of fibrin and a large amount of albumin, all but one boiling solid. The lymphocytes in all cases exceeded the polymorphonuclear cells, even in the cases with demonstrable lung involvement, and in those examined during the first week. Two cases of tuberculosis of the peritoneum were also studied, and the fluid was found similar in all respects to that occurring with tuberculosis of the lung.

Class III, the transudates, were characterized by a much lower specific gravity, the average of six examinations being 1,009 with 1,006 the lowest, and 1,012 the highest. They contained regularly less albumin and fibrin and the lymphocytes were in excess in all uncomplicated cases where the cells were not too degenerated to be counted.

Class IV.—The acute infections. It is a source of regret that this class is so incomplete. Many observers, however, have found that the cases due to acute infections have a relatively high gravity and contain as much albumin as the tuberculous effusions, but differ from the latter in the predominance of polynuclear cells, as is shown in Cases XIII and XV.

From a study of these cases we must conclude that all effusions within the pleural cavity are to be considered gravely, as a large majority of them are of tuberculous origin. We must realize that though a positive history is of the utmost importance, a negative one is absolutely valueless in excluding tuberculosis, and that pleurisies due to "cold" and "rheumatism" are legends which have come down from ancient medicine. Osler[17] recognizes three groups of serous effusions: (1) Pyogenic; (2) metapneumonic; (3) tuberculous; and in the absence of a pneumonia or a septic condition he considers the very presence of a pleural exudate sufficient to raise the question of tuberculosis. Concerning rheumatic cases, Osler mentions the following: A girl of sixteen, who had had two attacks of acute articular rheumatism with valvular involvement, was admitted to the hospital with chorea and an acute arthritis. While under observation she developed a sore throat, fever, pain in the left side, and urgent dyspnea. She died and at the autopsy the cardiac valves showed signs of ancient and recent inflammation, and the left pleura was the seat of an acute tuberculous process.

In the complete examination of effusions we have a means of diagnosis, not infallible of course, yet one in which we can place considerable confidence. It is a method well adapted to the needs of the busy practitioner, as neither guinea pig nor a thermostat is required. Noting the amount of fibrin, determining the specific gravity, and estimating the percentage of albumin by boiling with acetic acid, take but a few minutes. The fluid is then centrifuged for five minutes and the sediment removed by means of a glass pipette to a slide, dried by heating *very gently* and stained with Wright, Jenner, or gentian violet. The cells are usually numerous, so it takes but a short time to make the count. The fluid should be examined at once, as the cells degenerate quite quickly on standing. Gentian violet may be dropped on the sediment before it dries and a wet mount be made.

With proper facilities the clot should be digested, as suggested by Jousset, and the centrifuged product examined for tubercle bacilli.

Do not tell your cases of pleuritis that it is "only a little pleurisy" and send them on their way rejoicing, with a prescription for iodine, and never a word about fresh air. Moore[18] wisely says, "We are to think of pleurisy as an indication of some general

morbid condition and more often of some bacillary infection, and not to imagine that it is a mere affection of the pleura." Tell them that it is probably caused by the tubercle bacillus; assure them that they will get well, and warn them that they must take especial care of their health for a number of years lest a more serious condition ensue.

By such advice we will avert many cases of pulmonary tuberculosis.

ACUTE MASTOIDITIS, ITS PREVENTION, DIAGNOSIS, AND TREATMENT.

BY JOHN J. THOMSON, M.D.,

NEW YORK.

ACUTE mastoiditis occurs either following an acute suppurative process in the middle ear or as an accompaniment of a chronic process in the tympanum, the latter being more frequent on account of the general tendency to neglect cases of chronic otorrhea. The best preventative treatment of acute mastoiditis occurring during an attack of acute otitis is the proper treatment of the latter condition itself. The patient should be kept in bed for several days at the onset of the attack and not allowed to attend to business affairs. It is sometimes difficult to insist on this, especially after the membrana tympani has broken and the acute pain has subsided, but it will undoubtedly shorten the period of convalescence by several days, and frequently prevents the discharge from becoming permanent. The rest in bed should be insisted upon for two or three days, and particularly as long as any mastoid tenderness is present. It is the attempt to continue business while middle-ear suppuration is in the acute or subacute stages that causes so many of them to become chronic. A good cathartic should be given and repeated as frequently as is necessary to keep the bowels moving freely. Calomel followed by a saline is preferable for this purpose. If the attack is very acute, the temperature elevated, and the pulse rapid frequent small doses of tincture of aconite are sometimes of value. The first and most important procedure, however, is to give vent to the pus and accumulated secretions by an early and free incision in the membrana tympani. This should be done in every case of acute suppurative otitis media as soon as any bulging can be demonstrated. It is a popular fallacy that paracentesis is unnecessary after the drum membrane has ruptured spontaneously. The absurdity of this is at once apparent when we consider that a small perforation may be present in the upper part of the drum sufficiently large to allow the discharge from the canal to be copious and to relieve all pain, and yet leave the middle ear at all times filled with pus in contact with the delicate mucous membrane. The continued inflammation induced and maintained in this way is the most potent factor in the production of thickening of the membrane and intratympanic adhesions, and the permanent deafness that so frequently remains after the suppuration itself has ceased. A free paracentesis, then, is the first and most essential step in the treatment of acute suppurative otitis media and the prevention of mastoid involvement, regardless of the absence of pain or the freedom of the discharge. It should be performed under a general anesthetic, either nitrous oxide gas or ethyl chloride sufficing, and it should be done by one sufficiently skilled in its performance to insure a large opening in the proper position. Occasionally, in adults of phlegmatic temperament, local anesthesia may be used, but this frequently results in obtaining only a puncture instead of an incision, on account of the difficulty the patient experiences in remaining quiet when the knife is felt on the drum, even though it produces no actual pain. It may seem to a good many who have seen ears suppurate and get well in six weeks or so that I have laid undue stress on the advisability of early paracentesis, but the damage done by delay is not always apparent until after the lapse of several years, when the tests for hearing will show an ear functionally very deficient. In other cases the result of delay is immediately apparent in the onset of mastoiditis, or the persistence of a chronic otorrhea. After free drainage is thus established it is essential to maintain it by a daily inspection of the perforation in the membrana tympani; and should it show a tendency to close, it should be reopened as frequently as is necessary to maintain perfect drainage for the pus in the lowest part of the tympanic space. The canal should be regularly douched with at least one quart of hot bichloride solution every two hours. If it is possible to pack the canal afterward with a strip of gauze carried as far as the perforation, this will add to the drainage; but owing to the fact that it requires frequent changing, in any but hospital cases this is impracticable, and the douching alone is sufficient. As otitis media generally has its origin in some infection from the nose or nasopharynx, it is important to keep those parts cleaned with an alkaline solution, best applied by means of an atomizer.

A form of treatment that has recently come into use, in acute middle-ear suppuration, not so much in this country as abroad, is that suggested by Bier. It consists in producing a passive hyperemia of the

ear, by encircling the neck with an elastic band for twenty-two of the twenty-four hours each day. It is claimed that by retaining more serum in the affected region, its bactericidal action overcomes the resistance offered by the bacteria present, and the infection is thus rendered inactive. It has not met with many advocates in America, and my personal experience with it has been too meager to warrant my doing more than simply mentioning it.

In speaking of the prevention of mastoid trouble it is necessary to mention chronic otitis media and its care. Chronic otitis is probably the most prolific cause of acute mastoiditis. The infection is always present, and it requires only some increase in the discharge or the accidental entrance of some of the infected material into the mastoid cells to precipitate an acute attack. On this account chronic otorrhea deserves far more careful attention than it usually receives. If any necrosis be present in the bone it should be carefully removed through the canal if possible, or even by a more radical operation. Any adenoid vegetation should be carefully and thoroughly removed from the nasopharynx and the general condition of the patient attended to. Such local treatment as is demanded in each case should be faithfully given.

If, in spite of all our precautions, mastoiditis should develop, it is readily diagnosed in the majority of cases, only occasionally offering difficulties in this respect, unless it complicates some systemic disease. When dealing with middle-ear trouble we should always be on the lookout for mastoid involvement. About its first indication is more or less tenderness over the mastoid region. The precise location of the pain is of considerable diagnostic significance. Tenderness will nearly always be found over the mastoid tip in every case of otitis media, even in the serous variety, and it does not indicate involvement of the mastoid bone. On the other hand, tenderness to pressure manifested only when considerable force is exerted over the mastoid antrum points to an extension of the process from the middle ear to the antrum itself, while if it extends downward from the antrum toward the tip the mastoid cells have probably been attacked. Slight tenderness may remain for several days without requiring operation, and in 90 per cent. of cases will clear up. On the other hand increasing tenderness, even though there be amelioration of the other symptoms, must always be regarded with due respect. Pain is not by any means a constant symptom; in fact, it is rarely present. Instead of being localized to the mastoid region, it assumes the form of a headache, which may be greatest on the affected side. Pain is more liable to be troublesome in chronic mastoiditis than in the acute variety. Temperature is of small diagnostic value. In children we frequently find some elevation, but it rarely reaches higher than 99° to 100° in adults, unless some more serious condition than a simple mastoiditis exists. When we do have an elevation of temperature it is of value in connection with other symptoms, but its absence means nothing, as in the most extensive involvement of the mastoid it is frequently normal, and almost invariably reaches a higher point after operation than before. The position of the head is somewhat characteristic at times. Owing to the inflammatory action extending to the sheaths of the muscles attached to the mastoid tip, there is a tendency on the part of the patient to hold the head inclined to the affected side and to avoid movement as much as possible.

Sagging of the posterior membranous canal wall has been considered a valuable symptom of mastoiditis, and is frequently the deciding point when operative interference is in doubt. This is probably produced by extension of the inflammatory process from the antrum to the periosteum of the canal, causing the soft tissues to swell and partially obstruct its lumen. By some men this is considered almost a pathognomonic symptom; but it has always seemed to me that the same condition might be produced by extension of inflammation from the tympanic cavity itself without there being pus formation in the mastoid. If this tumefaction is present it is important, in making our paracentesis, to extend the incision well on to the canal wall.

A symptom of the greatest importance, and one that is very often overlooked, is the amount, and variation in the amount, of discharge. A moment's consideration will show the value of this symptom. The middle ear being a comparatively small cavity, it is possible for the membrane covering its walls to produce only a certain amount of discharge. If this is markedly increased it shows undoubted involvement of the other spaces, namely, the antrum or the mastoid cells.

I have frequently been able to diagnose mastoiditis requiring operation, practically on this symptom alone. Again, if we have a case discharging freely a small amount for a couple of days, and then suddenly the amount increase two- or threefold, it is fair to presume that some new source of supply has been added to that already existing. These remissions and exaggerations in the amount of discharge may occur several times, and, to my mind, they offer one of our best diagnostic points, especially in adults.

Swelling, edema, and redness are late symptoms, and when they are present of course there is no doubt in our minds regarding the diagnosis. We should not wait for them to appear, particularly in adults, as a most destructive process will exist without the slightest swelling. In children they are almost constant symptoms, and often the very first to draw our attention to the ear. Owing to the softness of the bone before four years of age, perforation externally is the rule. This usually occurs early in the course of disease, with attendant swelling and redness, and these symptoms mark the presence of a subperiosteal abscess. Swelling, therefore, is most important in children, and is one of our best aids in diagnosis, on account of the difficulty in estimating tenderness; on the other hand it is a rare thing to find it in adults except in cases far advanced. Occasionally a slight tumefaction of the tissues in this region can best be discovered by a comparison of both sides. It may cause the auricle to be protruded slightly more than its fellow, and the mastoid region occasionally presents an appearance of prominence without any appreciable increase in the thickness of the soft parts.

Symptoms of absorption are occasionally well marked in ambulatory cases of mastoiditis as well as in those that are more acute. Within a month I have operated upon a case of this nature. The child had a profuse discharge from the ear for several weeks and was gradually running down hill, but nothing occurred during that time to draw attention to the mastoid. At the end of about six weeks the mastoid swelled and became slightly tender. On operation a large cavity of pus was found in the mastoid, which fact explained both the large quantity of discharge and the general symptoms of absorption. These constitute the principal symptoms of acute mastoiditis, the most important of which are tenderness, swelling, and the large quantity of discharge. The large majority of cases which are

taken early clear up without leaving any serious results or markedly impairing the hearing. If a case showing mastoid tenderness be seen early, that is, within the first twenty-four hours, the treatment already outlined for acute otitis should be commenced at once, and an ice bag or an ice coil applied to the mastoid process. Very rarely any good is to be accomplished from the use of ice, but occasionally it relieves the pain if any is present. It should not be continued longer than thirty-six hours under any circumstances on account of its tendency to mask a serious condition in the bone. I have seen mastoids full of pus in which both the pain, and swelling and even the tenderness had entirely subsided under an ice coil only to give trouble again in a short time. After the lapse of thirty-six hours local application of either heat or cold to the mastoid itself have practically no effect, but if in order not to appear negligent it is necessary to do something, dry heat is preferable. The Bier treatment is occasionally used in the early stages of mastoiditis, but owing to inexperience with it I am unable to say what virtue it really possesses. At best it should be used only by those familiar with it, as its employment entails some danger. The damming back of the circulation in persons with hard arteries or cardiac lesions is liable to induce cerebral hemorrhage, etc., and in such cases the Bier treatment should not be used. If, after a few days, the tenderness does not subside the question of operation presents itself, and it is frequently a difficult one to decide. It is not desirable to open a mastoid which is simply congested, and on the other hand it is occasionally embarrassing to find a mastoid that has been under observation, entirely disintegrated at the time of operation. Where there is any doubt I think it is conservative surgery to operate early, not only to prevent extension to such important structures as the sigmoid sinus and the meninges, but to preserve the hearing. Some men go so far as to advise operation on the mastoid for the purpose of giving drainage from the middle ear, even though no mastoid symptoms are present and no involvement is suspected. While I consider this too radical for general application, there is no doubt the maintenance of posterior drainage conserves the hearing to a remarkable degree. The operation, if done early, is as safe as almost any, requiring the administration of an anesthetic, while if delayed too long a much larger area of bone requires to be sacrificed, the patient's general condition is not so favorable on account of continued absorption, and a thrombosis of the lateral sinus, cerebral abscess from direct extension, and meningitis may be induced. The condition can be well compared to appendicitis. One cannot tell precisely what is present until the time of operation in either case. In appendicitis it is considered more safe to do an exploratory operation than to take any chances, and I think the same principle holds good in dealing with mastoiditis. Undoubtedly, an occasional mastoid is opened when recovery would have taken place without operation, and one case of this kind leaves with the casual observer the impression that it is of frequent occurrence, while on seeing a thorough disintegration it is considered exactly what was to be expected. The more familiar one becomes with the consequences of palliative treatment long continued, the stronger is the inclination to operate where a reasonable doubt exists. After observation of at least five hundred operations at the Manhattan Eye, Ear, and Throat Hospital I cannot recollect having seen more than six or seven healthy mastoids opened. To illustrate the difficulty of positive diagnosis I will cite a case occurring about six weeks ago. Following a severe attack of grip the patient, a man of about thirty years, developed acute otitis media in the left ear and three days later in the right. I saw him on the second day of the onset of trouble in the second ear, and immediately did a paracentesis on both drums. Both mastoids were about equally tender for the next five or six days and there was free discharge from both canals. His general condition was very poor. He was anemic and showed plainly the effect of his illness. At the end of ten days the physician in charge of the case telephoned me that the amount of discharge from the left ear had greatly increased, as had also the area of mastoid tenderness. I saw him that day, and the two ears presented almost the same condition. Both mastoids were tender and painful, and, with the exception of the difference in the amount of discharge, apparently they were identical. His leucocyte count was 17,000 and temperature about 103 degrees, so I operated immediately on the left side. It would be difficult to imagine a more thoroughly necrotic mastoid. The necrosis had progressed to the lateral sinus, which was covered with protecting granulation throughout one inch of its course. After seeing the condition on that side there was not the slightest doubt in my mind that the other side was nearly as bad, but on account of his poor condition and the time of anesthesia required, owing to the extent of the disease, we decided it would be better to wait a few days before operating upon it. After three more days of careful treatment the discharge ceased, the mastoid tenderness disappeared, and apparently there is no further trouble there. Here were two ears in the same individual, necessarily under the same conditions of personal resistance and about as much alike as possible, one developing an extensive destruction of the mastoid, the other recovering entirely. I relate this case simply to show how difficult it is to be positive in our diagnosis or prognosis, and in addition it illustrates what I have already stated, that it is much safer to operate when any doubt exists than to take dangerous chances by waiting. It would have been very much better to have opened the one which recovered than to have left the other a day longer, in which time a thrombus might have been formed in the sinus. A somewhat similar condition occurred in a boy of eleven years. There was no history of discharge from the ear, and at the time of examination the drum head and surrounding parts appeared perfectly normal. There was very slight edema with tenderness over the mastoid, and the temperature was 101 degrees. The boy, though not feeling very ill, showed some signs of septic absorption and I decided to operate upon him, although I am free to confess I would not have been surprised to find very little or no trouble at all in the mastoid. The mastoid bone itself gave every sign of being healthy until the plate covering the lateral sinus was reached, when a large perisinus abscess was discovered. Taking into consideration just such cases as these, in which it is impossible to tell the exact condition, I think to operate is the most conservative course.

As to the operation itself, considerable improvement has been made in the technique within the past few years. Instead of simply opening the mastoid antrum and allowing the pus to escape, in the majority of cases, the entire process including the tip is thoroughly removed in an effort to avoid recurrence from remaining infected cells.

Each operator usually follows a technic of his own, some advocating a "T" shaped incision in all

cases, others only when it is necessary on account of the extent of the necrosis. The manner of procedure is unimportant; it matters little whether we begin the excavation of the bone at the antrum or at the tip, so long as every particle of necrosis, as well as parts that are liable to become necrotic, be removed. The cells behind the sigmoid sinus and those in the zygomatic region should be opened, even though in doing so the dura or lateral sinus be exposed. Such exposure rarely does any harm, whereas a few necrotic cells covering them will continue the discharge and endanger their integrity. This is where the greatest liability to faulty technique exists, because, when apparently healthy bone is reached, one who is not familiar with the vagaries of mastoiditis is tempted to desist from its further removal. If this be done even large sized cells filled with pus may be left in the region of the mastoid tip. It is of considerable importance to leave a bone wound of a favorable shape for healing—that is, to have it as shallow as possible and wide at its bottom. When this is accomplished there is not so much tendency to the formation of a fistula leading into the antrum.

A portion of the prominent posterior canal wall and anterior mastoid margin should be removed in order to allow the soft parts to fall in. This renders the cavity more shallow, requiring less time to fill with granulation, and it leaves less deformity after cicatrization has taken place. The principal object then is to remove, in the most thorough manner, all bone that has already undergone necrosis and, in addition, that which may at any future time do so. When mastoiditis has developed in a case presenting granulations in the tympanum, and where there has been a chronic offensive discharge, a simple mastoid operation is usually inadequate, and the radical Schwartze-Stacke operation will be required.

In conclusion I will say just a word about the after-treatment in operated cases, because that usually falls to the lot of the general physician. It requires a great deal of care and patience and in the most favorable cases healing requires at least six weeks. It is our aim to force the wound to granulate from the bottom. Occasionally the granulations form more rapidly toward the surface than they do in the antrum region. When this happens it is essential to destroy them, either by cutting them with a scissors, or by a caustic of some kind. Ortho-chloro-phenol is very useful for this purpose. If the condition be observed early enough firm packing at the margin, with gentle packing in the deeper parts will control the excessive granulation. It may be necessary to stimulate the granulation with balsam of Peru, or by rubbing them with a cotton-wound applicator. Another important thing is to prevent the skin from dipping into the wound, because its lowest point necessarily marks the level to which the granulations will grow. If it is allowed to dip in before the excavation is filled a depression results. In packing the wound it is advisable not to let the gauze slide over the skin margin because the inward growth of the epithelial cells is thus aided. At each dressing the skin should be gently pressed back. Frequently a fringe of granulations will form all around the margin of the wound, offering an insurmountable barrier to the epithelial cells. This should be left until the central granulations are sufficiently high and then cut away. The epithelium will usually rapidly spread from all directions when this is done. Unfortunately, in spite of the most careful technic at the time of operation, and the most skillful dressing, we are occasionally forced to operate a second time. The wound does best if dressed about every other day. The middle ear should be drained by a piece of gauze inserted into the canal and changed at each dressing. If the wound shows a tendency to become sloughy a few moist dressings of corrosive sublimate usually cleans it nicely. While treating the wound itself it is most important to look to the general health of the patient. He should be allowed out in the air and sunshine as soon as possible and everything done to improve his metabolism.

HAY FEVER AND PERSISTENT BRONCHIAL ASTHMA RELIEVED BY TREATMENT DIRECTED TO THE ANTRUM OF HIGHMORE.

By JACOB E. SCHADLE, M.D.,

ST. PAUL, MINNESOTA.

Three weeks ago Mr. W., aged fifty years, was referred to me by his family physician for advice regarding a nervous nasal catarrh and bronchial asthma from which he had been suffering almost constantly for a period of two years. In the autumn of 1904, while on a visit to the St. Louis World's Fair, he contracted what he supposed to have been a severe "cold in the head," which was followed by asthmatic seizures. This condition of things continued for some time, when it was determined that his case was one of hay fever. According to the patient's statements, he suffered thereafter in the winter as much as in the summer. The asthma was principally nocturnal, causing much discomfort and inconvenience, the patient being compelled to sit up through the night and sleep in a chair to obtain relief. He depended on the effects of antispasmodics, and became more or less addicted to their use. The usual palliative remedies recommended for hay fever, as well as the generally recognized medicaments for asthma, had been repeatedly tried without giving satisfactory results.

When this man first came to me he was in great distress from both the hay fever and the asthma, though otherwise he was healthy and robust. On examination his nose was found to be absolutely stenosed, the mucous membrane being edematously congested and swollen, thus rendering nasal respiration utterly impracticable. After reducing as much as possible the acutely swollen mucosa by the use of cocaine and adrenalin, it was observed that chronic hypertrophic rhinitis existed.

The eye symptoms of hay fever were characteristic—injection of the conjunctival vessels, burning and itching sensations, and hypersensitiveness to light. The throat symptoms presented the usual subjective sensations peculiar to the disease.

Taking the history of the case into account, as well as the array of neurotic symptoms, I diagnosed the condition hay fever asthma. As for a number of years I had been making observations and experiments along the antral theory of the disease, it occurred to me that the present case was typical, and would afford an excellent opportunity to test the correctness of the theory and the virtue of the method of treatment which I had pursued with satisfaction in many other cases in the period mentioned. Accordingly, both antral cavities were irrigated with a warm boric acid solution until the return fluid was clear and perfectly free from sediment. The hypersecretion of

the cavities was marked, and it required considerable irrigation to clear them.

The sinuses were then freely insufflated with thymol iodide, and the patient was advised to return the next day for further observation and treatment. He presented himself the following day as requested, when it was ascertained that the nasal symptoms had been ameliorated, but the asthma was the same. The hypersecretion of the antra was markedly lessened. He received the same treatment for five successive days, each subsequent visit showing an improvement over the preceding one. On the night of the third day of the treatment he found that he was able to lie down and sleep, being interrupted, however, several times in the night by slight asthmatic attacks. Ever since the third day of treatment all the symptoms have disappeared, and now I see him occasionally for purposes of observation and a study of the behavior of the antra.

Other treatment, apart from what is above described, was not required. Neither was his environment changed. This case illustrates, in a rather conclusive way, the intimate relationship existing between a morbid state of the maxillary sinuses and the local and general phenomena symptomatic of hay fever. The antral theory embodies these factors, namely, that the antrum of Highmore provides the secretion that forms the agent that causes the local irritation in the sinus and nasal passages alike.

The various agents producing irritation of the antrum come from without, and when they are brought in contact with the mucosa an inflammatory disturbance is initiated which involves the sensitive nerve endings and secretory nervous fibers of the mucous membrane. Primarily, it is this inflammation and consequent secretion of the cavity that form the active factor in the production of the disease. The discharges proceeding from the antrum into the nasal passages inaugurate the nasal and nervous phenomena, owing to their irritative properties.

The central and sympathetic nervous systems become thus disturbed by the local disturbance, and neurasthenic symptoms manifest themselves. To abort or control an attack of hay fever, this theory presumes that treatment of an antiseptic character must be directed to the inflamed and hypersecreting antrum.

A POSSIBLE DANGER IN THE THERAPEUTIC USE OF OSMIC ACID.

By ARTHUR E. HERTZLER, M.D.,

KANSAS CITY, MO.

At the recent meeting of the Western Surgical Association J. Rilus Eastman reported a case in which hematuria followed the injection of a solution of osmic acid for neuralgia. No other evidence of renal involvement was noted and the patient recovered. Slight as was the disturbance, it points to a possible danger from the therapeutic use of this agent. The essayist offered no explanation for the urinary disturbance noted. This leads me to report, as of possible interest, some observations made with this chemical in my researches on the peritoneum.

Osmic acid, in common with several other minerals used in microtechnique (*e.g.* silver nitrate and gold chloride), acts differently from true stains in that a definite reaction takes place, producing a precipitate of a more stable compound of the metal. This result takes place in recent tissue only—tissues still living or within 24 to 48 hours after death. These chemicals act on definite substances in the tissue. Silver nitrate is the only one of this group which has been definitely worked out.* With this substance a combination with the chlorides of the tissues takes place, forming the silver chloride. This compound is nontoxic when exhibited by the mouth but rapidly fatal when injected into the blood-vessels or into the abdominal cavity. This may be easily demonstrated by injecting a large quantity of normal salt solution into the free peritoneal cavity of an animal and then following it by the injection of a solution of silver nitrate, in a much smaller amount than would be required to combine with the chlorine present in the salt solution. There results from this a precipitation of silver chloride. The NaCl not required to combine with the $AgNO_3$ remains as an innocuous solution. The same results are obtained by allowing the reaction to take place in a beaker and afterwrad injecting it in the peritoneal cavity. In this latter experiment larger masses of the AgCl are formed and effects are in consequence less prompt. The animal, as the result of either experiment, dies after a few hours. Death is due for the most part to an absorption of the particles precipitated, first into the connective tissue spaces and then into the blood-vessels. (An argument incidentally in favor of the blood-vessel rather than the lymphatic route of absorption.) These particles are transported through the vessels to the various parts of the body (as is seen in the argyria from the therapeutic use of silver). Curiously enough the kidney capillaries are the depositaries of a greater amount than those of any other parenchymatous organ. The deposition is accompanied by a petechial hemorrhage in many parts of the kidney.

With osmic acid it is more difficult to trace the reaction. We know, however, that a precipitate forms not unlike that of silver except that the particles are larger. This holds good at least as used in the peritoneal cavity. What elements in the tissue combines with the acid is not known. However, when a dilute solution of the acid is injected into the free peritoneal cavity, particles may be discovered in the kidney just as in the case of the silver chloride, with the small hemorrhages accompanying, which is the interesting point in the present consideration.

It has long been known that in argyria a large number of granules are found in the pericapillary connective tissue. They are surrounded by an increase of fibrous tissue, probably the result of previous capillary hemorrhage. That no great mischief is done can be readily understood by the slow process of deposition.

The small amount of osmic acid used in the treatment of neuralgia is probably not great enough to jeopardize the life of the patient. Still these observations suggest that there is a limit to the amount of the chemical which can safely be used in our therapeutic endeavors.

*Hertzler, A. E.: The Morphogenesis of the Stigmata and Stomata of the Peritoneal and Blood-vessel Epithelium. Transactions of the American Microscopical Society, 1901.

A Grewsome Reminder.—When the floor of the operating theater of the old hospital at Canterbury, England, was torn up the other day, the rings were discovered through which were passed the cords for tying patients down on the operating table prior to the discovery of anesthetics.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, September 8, 1906.

A WARNING TO THE INTENDING STUDENT OF MEDICINE.

THE Association of French Physicians has recently issued a circular to candidates for the bachelor's degrees in letters or science, and to their parents, warning against taking up the study of medicine without a full knowledge of the "miseries of the profession" and the burdens which await those who aspire to a medical career. The following is, in part, the text of the circular: "As you are about to end your academic studies, and as you are now facing the choice of a career, you are doubtless interested in studying the various advantages of each vocation before making a decision which may affect your entire future. The different liberal professions may have claimed your attention, and among them the medical profession, which passes wrongly for an easy and lucrative calling. This manifest error is current among the French public, and is most dangerous, for it leads to the gravest consequences, both for yourself and for us. It has seemed to us, therefore, both necessary and useful to enlighten you as to our real social position at the present day, through the following facts, which are given without a trace of exaggeration.

"The overcrowding of the medical profession in France has to-day obtained the extreme limit of endurance. Our nation figures now among the European countries where there is the highest number of physicians in proportion to the population. (There are 10.4 physicians in France per 10,000 inhabitants.) The consequence is that every day we and our families are experiencing greater financial distress. And yet, a crowd of thoughtless youths continues to enter upon the study of medicine, and the number of medical students is manifestly greater than could possibly be demanded in the future. Medicine is one of the most burdensome callings, and presents but meager chances for the enjoyment, or even the repayment, of the capital invested (at least 30,000 francs) in study and preparation—a sum which is absorbed without any guarantee of returns. On the other hand, the various industries, the different branches of commerce, and some of the other liberal professions offer, with the same investment, a far better, larger, and surer field for the activity and initiative of modern youth, without condemning their votaries, as does medicine, to complete inactivity, and consequently to failure, and often to poverty, in the presence of the slightest illness."

The letter closes with an appeal to the better judgment of the reader, and bears the signatures of nineteen physicians, each representing one of the district societies composing the French national association.

There is no doubt that the statements contained in this circular are correct, and we think that the action of the French association deserves imitation in other countries, including our own, where the overcrowding of the profession is becoming serious. Such a warning should present a convincing array of statistics concerning the earnings of the medical man, and should show clearly the number of years of waiting and of preparation that are in store for the young physician. These circulars should be sent by the local medical societies, to each college, high school, academy, and preparatory school in their district. Presidents and principals of academic institutions should be supplied with additional data, which might enable them to advise prospective medical students intelligently.

Those who have within them the true calling of the physician; those who are willing to sacrifice much for the sake of entering a field for which they are fitted by nature, and in which their love of the art will help them over many a thorny place, will not be deterred by such warnings, nor will those be affected whose means allow them the pursuit of any career without much thought as to its ultimate financial rewards. But a timely warning uttered by authority may be the means of preventing many a young man from taking a step which he will possibly regret to the end of his days.

A PLEA FOR THE BOTTINI OPERATION.

WHAT operation to do in any given case of prostatic hypertrophy is a question which cannot by any means be considered fully settled. Those who have mastered the technique of the Bottini procedure bring forward many good reasons for their preference, and claim, naturally, that the objections are largely outweighed by the favorable features. Freudenberg, who has recently reported a series of 152 cases treated by this means (*Die Heilkunde* No. 5, 1906), believes that among the most potent arguments in favor of the Bottini operation are the facts that it may be carried out under local anesthesia in most cases, that it does not confine the patient to bed as long as does the more radical operation of prostatectomy, and that, being less extensive in character, it is also more readily adapted to the treatment of the disease in aged or weak patients. Freudenberg also claims that it is equally indicated in younger men, who are very apt to refuse an operation which will render them impotent. This complication is avoided by the Bottini operation, and the improvement in the general health which follows also exerts a favorable effect in those cases in which impotence is already partially developed.

The procedure seems to be particularly indicated in cases in which the prostatic hypertrophy is slight or moderate, although it may be equally effective in advanced cases. In the latter instance, however, we have to deal with the liability of a recurrence and the necessity of a more extensive exposure. In prostatectomy the size of the gland makes little dif-

ference, and this operation, moreover, is specially indicated when the middle lobe is hypertrophied and pedunculated. In such cases, of course, it is merely necessary to remove the offending segment, and then the lateral lobes may, in addition, be treated by the application of the galvano- or thermocautery. As it may be impossible in certain instances to determine exactly the relations between prostate and bladder by the cystoscope, a suprapubic prostatectomy may prove the operation of choice in such cases. Cystitis, with an acid urine, as well as pyelitis of a moderate degree, do not constitute contraindications to either procedure, but nevertheless the aim should always be to improve the condition of the urine before attempting an operation. When the reaction of the urine is alkaline, a Bottini operation should not be done until this has been changed, otherwise the slough will become incrusted with a phosphatic deposit. During the after-treatment the precaution should always be taken to keep the urine acid in reaction.

A summary of Freudenberg's statistics is of interest. He performed the Bottini operation 180 times in 152 cases, mostly of prostatic hypertrophy and a few of carcinoma. The age of the patients varied from 41 to 82 years, the average being about 65. Only cases with chronic long standing urinary retention were operated upon, the acute cases being treated by other means. Out of this total number a good result was obtained in 129 (84.9 per cent.); in 11 (7.9 per cent.) the procedure was a failure, and in the same number death followed the operation.

THE THERAPEUTIC VALUE OF ANTITHYROIDIN.

It is generally believed that the functions of the thyroid and parathyroid secretions are concerned with the neutralizing of certain metabolic poisons produced by the organism and circulating in the blood. Lesions in either one of these organs have likewise been held responsible for the unique and characteristic symptoms associated with exophthalmic goiter and kindred affections, and to the parathyroids has recently been given an increasing importance in the production of these. The results of operative removal seem to show that the latter is associated with a train of symptoms resembling in all respects those of Graves' disease; and it is also followed by a decrease in the size of the thyroid gland. For the relief of the symptoms which accompany exophthalmic goiter and similar diseases, the use of antithyroid extracts or sera has been proposed on the theory put forward by Gauthier and Moebius, that the condition was due to hyperthyroidization. If it is ultimately proven that these remedies are curative, then it will be quite evident that excessive or at least changed secretions of the thyroid or parathyroid bodies are pathogenic factors in the etiology of the diseases previously referred to.

A test of this theory has been made the subject of a practical clinical experiment by Eisner and Wiseman (*New York State Journal of Medicine*, June, 1906), who used it in a series of twelve cases of typical exophthalmic goiter, the serum being obtained from the blood of thyroidectomized sheep. Several typical cases were also under treatment, in the majority of which the goiter, if present, became more or less reduced; but, taking all the cases together, the writers plainly state that at this time they are not justified in reporting a complete and absolute cure in any. They claim, however, that antithyroidin is a remedy which can be used successfully for the relief of the annoying and alarming symptoms in both typical and atypical cases, particularly as regards the tachycardia, precordial distress, and tremor. Improvement should follow in from three to seven days, and if it has not begun within three to four weeks the chances seem to be against ultimate benefit from the prolonged use of the serum. The cases which, according to Eisner and Wiseman, have yielded most readily to treatment, are those characterized by moderate goiter development, with slight exophthalmos and tremor. Although the enlarged thyroid did not return to its normal size in these cases, it became perceptibly smaller. Exophthalmos seems to be the most rebellious symptom, never yielding entirely to antithyroid treatment. It was found that the nervous symptoms improved as the heart became slower, and the feeling of fear which possesses many of these patients also disappeared. Another favorable feature which has attended the use of the serum has been the increase in weight which the patients have experienced, and the authors sum up their experiences by stating that in no case did they regret the trial of this remedy; it always proved itself harmless.

This report is certainly an encouraging addition to the others which have been published in the same tenor, and, although it is too early to base conclusions on the relatively small number of cases which have been published, there is, nevertheless, reason to hope that ultimately the administration of antithyroidin will prove to be a rational therapeutic method. At present its value in relieving symptoms must be admitted, and also the fact that it is not followed by any injurious results.

Consanguinity in the Etiology of Certain Dermatoses.

Intermarriage between blood relations has long been looked upon with disfavor among civilized peoples, for the offspring of such union has often been found to present anomalies of development or to be afflicted with diseases which are naturally ascribed to what is generally regarded as a violation of nature's laws. Nervous and mental disorders in the children seem particularly prone to follow such marriages, and among numerous other conditions for which no adequate explanation can be found, certain obscure dermatoses, such as xeroderma, ichthyosis, scleroderma, and albinism, have been attributed to the same cause. A very thorough investigation of this interesting subject has recently been made by Adrian (*Dermatologisches Zentralblatt*, No. 9, 1906), who believes that consanguinity apparently plays a less prominent rôle in dermatology than in neurology or psychiatry. In xeroderma pigmentosum, ichthyosis congenita, and albinismus universalis, to follow the characteristic nomenclature of the dermatologist, consanguinity must be regarded as an etiological factor of moment; indeed, in xeroderma it was found

in 11.8 per cent. and in ichthyosis in 12 per cent. of the cases. The appearance of the same disease in a number of children may also be regarded as an evidence of collateral rather than direct infection. A transmission of the disease to the next generation has never been observed in the case of xeroderma, and it is almost impossible in ichthyosis, because the afflicted individuals do not reach the procreative age. Although no figures are given relating to the occurrence of albinism, it is also frequently noted among the children of parents who are blood relations.

Therapeutic Applications of Diet.

The bodily metabolism, particularly as affected by diet, is a factor not to be lightly considered in the presence of any morbid state, while it is an influence of primary importance in the management of a group of diseases of which obesity, diabetes, gout, lithemia may be viewed as typical examples, and it is of scarcely less weight in connection with diseases attended with or followed by wasting. Dietetics is, however, not yet an exact science, but merely an applied art, based upon known facts and empirical observation. Foods have certain chemical and physical properties that may often be utilized with therapeutic advantage. It is true that all individuals do not react alike to the same articles, as also they do not to the same medicinal agents, and accordingly allowance must be made here likewise for personal idiosyncrasy. In concluding a brief discussion of this subject in the April number of the *Practitioner*, Dr. Robert Hutchison formulates a number of rules that may usefully be followed in the selection of a dietary for therapeutic purposes under varying conditions. The first injunction is, in the presence of acute disease, not to sacrifice the whole for a part. For example, it is often better for a dyspeptic patient to suffer some discomfort from the ingestion of food than to permit a lowering of the general vitality through excessive abstemiousness. In the next place, no article of food should be prohibited in the absence of good reason therefor. In the selection of food those articles should by preference be recommended that are acceptable to the patient and agree with him, although a reduction in the amount of any food that disagrees is as a rule better than its entire withdrawal. It is advisable, when possible, that any changes made in diet should be gradual rather than abrupt.

The Influence of Calcium Salts on the Nervous System of Infants.

In studying the effect of calcium salts on the motor centers of the cortex, Sabatani and others have found that the electric responses are diminished by the application of isotonic solutions of these salts, but increased when solutions of ammonium oxalate and similar salts, which absorb the lime from the cortex, are applied. These observations would naturally lead to the thought that a lack of calcium salts in the organism, particularly in the tissues of the central nervous system, would exert an important bearing on the production of certain varieties of convulsions to which children are predisposed. Quest (*Weiner klinische Wochenschrift*, No. 27, 1906) made this question the subject of careful investigations, using for his experiments young dogs which all came from the same litter, some of which he fed on a diet rich in lime and others on food from which the calcium salts were largely eliminated. He found that the animals in the latter class presented a marked increase in nervous irritability, and their condition was one akin to tetanus. The irritability of the cortex was not increased, however, nor did the chemical examination of the brain show any changes as regards the calcium content, but this may be due to the fact that the experiment was not continued over a sufficiently long period of time. These observations are by no means extensive enough to warrant the formulation of any practical conclusions, but they do show that the mineral constituents of the infant's food exert an important bearing on the nervous system, particularly, as it seems, the peripheral. Some day we may be able to employ this knowledge in the application of a more rational therapy in what are among the most common of the diseases of infancy.

Treatment of the Edema of Pregnancy.

Although in many instances the edema which comes on during pregnancy is accepted as a matter of course and receives little attention until some more alarming symptoms are added, the idea is gradually gaining ground that the venous congestion due to the pressure of an enlarged uterus is not the only factor in its production, but that it is almost always the result of a renal disturbance, although albuminuria may be absent at the time. It has been claimed that the condition might be favorably influenced by withholding sodium chloride from the diet, and the theory has been put to a practical test by Cramer in a series of cases (*Monatsschrift für Geburtshilfe und Gynäkologie*, Vol. XXIII, No. 4). Careful measurements of the ingested and excreted fluids, when the diet was free from salt and again when it contained it in ordinary quantities, showed that in all cases as soon as the salt was withdrawn there was an increase in the amount of fluid excreted and the edema was lessened. In some of these cases was the fetus in any way affected.

News of the Week.

Death List of the San Francisco Earthquake.—So far as it has been possible to determine, 452 persons lost their lives as the result of the San Francisco disaster, April 18. These are the figures given in the report of the local Health Department to the California State Board of Health. Two hundred and sixty-six of the victims were killed by falling walls, 177 perished by fire, 7 were shot, and 2 died as the result of ptomain poisoning due to eating "emergency" canned goods of poor quality. Four hundred and twenty persons were white, eighteen were Chinese, four Japanese, and ten not stated. Eleven were less than a year old.

An Experimental Filtration Plant for New York.—Bids have been called for by the Water Department of New York City for the construction of an experimental filtration plant at the Jerome Park reservoir. Observations will be made there as to the efficiency and expense of filtering the water, and the methods best suited to the needs of the city will be inquired into.

St. John's Guild.—The floating hospital of St. John's Guild has carried this season, up to September 1, 36,000 women and children. The seaside hospital has admitted in the same period over 2,500 patients for an average stay of ten days. The floating hospital discontinued its daily trips on September 1, but the seaside hospital will remain open indefinitely, all winter if the funds will permit. This season has been the heaviest in the

history of the Guild. Contributions for the continuance of work at the seaside hospital, which are requested, may be sent to the treasurer of the Guild, at its office, 501 Fifth avenue.

A New Hospital Car has been built for use on the Erie Railroad. It is 60 feet long, with two compartments—an operating room, 15 feet 10 inches in length, and a ward, 43 feet 10 inches in length. In the operating room are an operating table, instrument sterilizers, and lockers containing instruments and dressing material. The inside finish is of a composite board, without beading or carving of any kind, painted in white enamel; the floor is covered with white rubber tiling. The ward contains eleven brass bedsteads. Equipment boxes underneath the car are provided with crutches, splints, army stretchers, surgical implements, wrecking tools, and other accessories.

Increased Mortality in Chicago.—According to the report of Coroner Hoffman of Chicago, August was characterized by the highest death rate of any month in several years. There were 390 deaths in Cook County, as against 338 for July and 356 for April, the next largest month. The increase in the death rate is attributed to the excessive heat. There were twenty-seven deaths by heat, as against one for the month of July. Suicides also increased with the hot weather. There were thirty-nine during August, more than for any other month save February, when there were the same number.

One More Cancer Cure.—Dr. Otto Schmidt of Cologne is reported by cable from Berlin to have discovered and cultivated the cancer bacillus and to have proved its pathogenicity by injections into animals which were followed, he claims, by the development of cancer. He asserts, further, that he has elaborated from cultures of this bacillus a product which is curative of malignant disease in its early stages. Dr. Schmidt refuses to divulge the nature of his alleged remedy, but says it is not an antitoxic or bacteriolytic serum. It is not stated whether this is the same remedy Dr. Schmidt had a year or two ago, or whether it is a new one.

Application of the Oslerian Age Limit.—Dr. Ray Lankester, Superintendent of the National History Department of the British Museum, has been notified that he will be retired in May of next year, when he will have reached the age of sixty years. In order to accept the position Dr. Lankester resigned the Linacre Professorship in the University of Oxford, a life position, with six months' vacation every year and carrying a salary of $4,500. His present salary is $5,000, but when forced to get out at the age of sixty he will have nothing but a pension of $1,500. Dr. Osler himself is now sixty years old, and there is some speculation whether he will retain the Regius Professorship at Oxford or will resign in favor of some one who has not yet reached his old-age limit.

Dr. William J. Mayo, President of the American Medical Association, received the degree of LL.D. from Toronto University on August 24. The degree was also conferred on Drs. Louis Lapicque of Paris and L. Aschoff of Freiburg, Germany, and eleven prominent members of the British Medical Association.

Captain Joseph Herbert Ford, Assistant Surgeon, U. S. Army, was one of the recipients of the Belilios prize for his contribution entitled "The Treatment of Dysentery," published in the *Journal of Tropical Medicine*, July 15, 1904. The other recipient was Captain J. G. Berne of the Royal Army Medical Corps, whose contribution with the same title was published in the *Journal* on August 1, 1904.

Dr. Lemuel W. Famulener has been appointed assistant professor of pathology at the Indiana University.

Dr. W. W. Keen of Philadelphia, received the degree of doctor of laws from the University of Greifswald, on the occasion of its recent celebration of the four hundred and fiftieth anniversary of its foundation.

Dr. A. H. Dollear of Jacksonville has been appointed assistant physician of the Illinois Western Hospital for the Insane, at Watertown.

Dr. William Seaman Bainbridge has been elected adjunct professor of surgery, and has been assigned to one of the clinics of that department in the New York Polyclinic Medical School and Hospital.

The Dunning Phthisis Camp.—The free open-air camp at Dunning for women suffering from tuberculosis, which is to be under the management of the Chicago Tuberculosis Institute, was opened September 3. Tents and cottages enough have been erected for the accommodation of twenty women in the early stages of consumption. Men patients are permitted to remain in the camp during the daytime.

A Health Officer Approves of Cigarettes.—The important news was telegraphed the other day from one of the Lake cities to a New York newspaper, that the Health Officer of the former had advised women to smoke cigarettes. "He had found," the dispatch reads, "that the society women here are addicted to the excessive use of tea, and attributes to its abuse the spread of heart disease among them. Tea acts as a stimulant, while nicotine depresses the heart, so that the one counteracts the effect of the other." It is to be hoped for the sake of the health officer's reputation as a physiologist and therapeutist, not to say a man of common sense, that this is only a silly season story.

A Sane Act of an Alleged Lunatic.—A man in Boyle County, Ky., recently made application to be committed to the Lakeland Asylum for the Insane. He told the trial jury that if permitted to remain unconfined he might murder his wife and three little children, and kill himself, after burning their home. He could not get over these insane impulses, and consequently he felt the need of restraint. The jury granted his request, and he went to the asylum from the court, expressing his joy in the assurance that his wife and children would no longer be in danger whenever the homicidal mania seized him.

A Reaction Against Opium Smoking in China.—There is a strong movement among the students and younger merchants in Canton against the practice of opium smoking, and a society for the suppression of the habit has been in existence there for some time. Recently an antiopium league was established in Honan, and the movement is spreading to other parts of the Empire. The Government, it is said, is about to appeal to the Government of India to consent to an annual reduction in the importation of opium into China, which will have the effect of extinguishing the trade within ten years, and it is said that the

Chinese will give force to this appeal by issuing an edict forbidding the use of opium by Government employees, and gradually reducing the cultivation of the drug in China, so as to end it entirely within ten years.

A Christian Science Miracle.—The press agent of the Christian Scientists in this city recently reported the wonderful cure of a woman into whose face some one threw carbolic acid, with results "too horrible to picture." Nothing is too tough for a C. S. healer, however, so she was taken in hand and demonstrated so forcibly that the lesions healed without a scar remaining. This is almost as convincing as the miracle performed by the C. S. young lady who found a litter of kittens born blind; she demonstrated to them so well the folly of being blind, that in a few days they were persuaded to open their eyes, and could see as well as any other kittens. The C. S. press agent ought to employ a medical censor to tell him when his miracles are commonplaces, before he publishes them to an amused world.

Lord Kelvin on the Atomic Theory.—In a recent letter to the London *Times*, Lord Kelvin enters a protest against the assumption that the atomic theory is disproved by the discovery of Sir William Ramsay and Professor Soddy, that helium may be derived from radium. This and the prior discovery by Ramsay of helium as an emanation from clevite, prove no more, he says, than that both radium and clevite contain helium, not that they have established the fact of the gradual transformation of one element into another.

Baths for the Tuberculous.—The Public Bath Commissioner of St. Louis has called upon the Board of Health for statistics showing which are the special centers of tuberculosis in the city, as he believes the baths should be established first in those districts. In four of the seven sanitary districts the number of cases reported for the past year ranged from 260 to 271, and in the remaining three from 192 to 249.

Suppression of Quack Advertisements in Michigan.—The Nottingham law, passed by the Michigan Legislature in 1903, has at last, after much litigation, been declared constitutional by the Supreme Court of the State. The law gives to the Medical Licensing Board of Michigan the power to revoke the license of any physician who is found guilty of obscene or offensive advertising. Certain newspapers and the advertising quacks fought the bill stubbornly for three years, but decency prevailed, and the State Board is now empowered to silence the worst of the charlatans.

Appointments to the Medical Faculty in Mexico.—Dr. José S. Saloma has been appointed to the chair of internal medicine, and Dr. Ernesto Ulrich to that of pathological anatomy, in the National School of Medicine in Mexico City, and both have become titular members of the Mexican Academy of Medicine.

Bequest to the North Adams Hospital.—In the will of the late S. Smith Joy of North Adams, Mass., the local hospital benefits in a bequest of $2,000.

Association of German Naturalists and Physicians.—The seventy-eighth annual meeting of this association will be held at Stuttgart, in the week from September 16 to 22.

Obituary Notes.—Dr. Hunter P. Cooper of Atlanta died of meningitis on August 24. He was born in Wilkes County, Ga., in May, 1860. He was graduated from the College of Physicians and Surgeons in this city in 1883, and, after a course of study in Vienna and Berlin, he began the practice of medicine in Atlanta. He was professor of anatomy and clinical surgery at the Atlanta College of Physicians and Surgeons, and was a prominent and active member of many medical societies and social organizations.

Dr. William Van Tuyl of Leavenworth, Kansas, died August 19 from disease of the heart. He was a graduate of the Kansas City Medical College in the class of 1889. He was a contract surgeon in the war with Spain, and served for several years in the Philippines.

Dr. Nathaniel Cass of Cameron, Texas, died August 20 after an operation for appendicitis. He was a graduate of the Medical Department of Tulane University in the class of 1882.

Dr. Irving Washington Hewit died in Spokane, Wash., on August 21, of Bright's disease. He was born at Delafield, Wis., January 13, 1854, and was graduated from the Medical College of Indiana in the class of 1883. He then began practice in Bellwood, Neb., where he remained until 1904, when the state of his health forced him to retire.

Dr. Byron W. Hinds of New Hope, Ala., died August 22 at the age of seventy-one years. He was a graduate of the Medical Department of the University of Nashville in 1866.

Dr. Edward D. Perkins of Washington died August 24. He was born in Castine, Me., and was for some time a teacher in the public schools. He subsequently took up the study of medicine at Georgetown University, taking his degree in 1895.

Dr. Nielson Abeel Baldwin of Brooklyn died at the Seney Hospital on August 20, at hte age of sixty-seven years. He was born in this city, and was graduated from the Yale Medical School in 1861.

Dr. John Hay Higgins of New York City died August 28, at the age of seventy-nine years. He was graduated from the College of Physicians and Surgeons in this city in the class of 1850.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENT, SANITARY INSPECTIONS, ANTHRAX, FREE MEALS, ETC. — MEDICO-LEGAL SOCIETY, DEATH REGISTRATION — ALLEGED INCREASE OF LUNACY — COSTLY ASYLUMS — FEEBLE MINDED — OBITUARY NOTES.

London, August 17, 1906.

Before the adjournment of Parliament a number of questions were treated discursively on the votes for the Home Office and the Local Government Board. More inspection of workshops was urged and, further, the possibility of inspective work done in the homes of certain workers. The prevalence of anthrax was said to be due to faulty legislation and the greed of manufacturers. Attention was called to the importation of poisonous woods. The Home Secretary on these and other complaints replied that he would consult the Local Government Board as to the inspection of certain industries. He had called for special reports on jam making and fish curing, and would soon do so about aniline dyes and poisonous woods. He regretted the increase of anthrax, but thought that to deal with wool at the port of entry would be too great a tax on the trade, so a special committee had been appointed at Bradford to deal with the detection of the disease and seek a remedy by chemical processes.

This is the sort of way officials generally discuss sanitary matters. They can appoint a committee or even a royal commission to shelve inconvenient questions or put off subjects which do not interest the mere politicians. The deaths from anthrax in 1900 were 37; in 1901, 39; in 1902, 38; in 1903, 47; in 1904, 50; in 1905, 59. But who cries out that these deaths ought to be prevented? The

manufacturers? No; they fear a tax on their trade. The workmen's representatives? No; they are intent on setting trades' unions above the law. The Government? No; they have to settle with the opposition more exciting topics. Only doctors and sanitarians continue to protest against this waste of human life.

Mr. Herbert Gladstone, in defending his office, said they had had very heavy work in reference to lunacy, that almost every day vaccination was hurled at his head, and that he had been tormented in private as much as or even more than in public by vaccination. This complaint illustrates the ways of the antis of all kinds who have no scruples as to how they endeavor to force attention on their prejudices. Another illustration is that, now Parliament has separated, they hasten to furnish the papers with letters to fill the space which is vacant, and the papers—many of them—print these letters as if they were of value. Yet it is quite understood by those "in the know" that the outbreak of this sort of correspondence is engineered by the paid agitators. It is held, too, by some close observers that many a "conscientious objector" has been put up to object to vaccination by the antis—his expenses being paid by them on a scale indemnifying him for loss of time. Yesterday I was amused to hear a gentleman argue that the cheapest way to insure vaccination would be to pay the father a shilling in each case. When, he argued, the "free and independent elector" will accept the "price of a pint" for his vote, a shilling would be an effective bribe to certain parents. I hesitate to admit that a considerable number of parents have fallen so far.

But it is certain that the idea of parental responsibility has been weakened by recent legislation, as well as by the advocacy of various measures. We are so used to the abuse of hospitals that we scarcely think of it in this aspect. Charity never fails, and so there are persons who always take undue advantage of it. They take it as a matter of course. They have free education, free medical advice, free drugs, free surgical instruments, and even free spectacles. In many schools free boots are obtainable for children whose footgear is defective. Finally, free meals for the children have been demanded by the educationists and sentimentalists, backed up by the labor party, and this week we have the report of a select committee of the House of Commons on a bill for providing meals for children in schools. This report seems a sort of compromise with principle for the sake of conciliating a faction. The "strongest government of modern times" is afraid to reject a demand from its extreme wing and refers it to a committee to effect some arrangement. It is obvious that the committee has scruples as to what these growing demands will lead to, and in order to escape responsibility throws it upon the local authority, which, it recommends, should have power to organize a scheme and to pay out of public funds for the accommodation of a staff and for the preparation, cooking, and serving of meals. The cost of the food before cooking is to be paid for by voluntary funds, *where available;* but in exceptional cases the uncooked food may also be paid for by the local authority. Talk of hospital abuse after that!

The Medico-Legal Society has been discussing the present methods of ascertaining the fact and cause of death, and, on the report of a committee appointed to consider the matter, has resolved that our methods are imperfect. Further, the society has appointed a deputation to wait on the Lord Chancellor in order to represent to him this view. The learned president, Mr. Justice Walton, will approach the Lord Chancellor as to the reception of the deputation.

One phase of the lunacy question is the propriety of confining certain persons in asylums. At a meeting of the Kent County Council on Wednesday a vigorous protest against the constant demand for further buildings was made. One of the council's asylums is now being enlarged, at a cost of £62,000, and a further demand was brought up by the committee to enlarge another to the extent of 300 to 400 beds, at an estimated cost of £190 per head. The chairman regarded these constant demands as deplorable, and said many persons certified as lunatics might be looked after in less costly establishments. He hoped the Royal Commission would be able to evolve some scheme of classification so that imbeciles might be received in less expensive homes than up-to-date asylums. Yesterday a similar protest was made by the Hampstead Guardians, who directed their clerk to bring before the Local Government Board some of their difficulties. The majority of those sent to asylums from the workhouse were aged people with senile dementia, harmless and yet inconvenient to mix with other patients. But the guardians regret to be obliged to send them to asylums and increase the statistics of lunacy when they would be better looked after in homes. They therefore approve the proposal of the London County Council to establish receiving houses which would serve the purpose.

Dr. Fraser of Weston-Super-Mare died on the 8th inst., aged 54. He was taken ill on July 9, on which day he had attended an inquest and afterward performed an operation. He was a surgeon-colonel in the volunteer engineers.

Dr. F. B. O'Flaherty of Liverpool died on the 1st inst., aged 45. He was an Edinburgh graduate M.B. and C.M. and took the D.P.H. of Cambridge. Many years ago he practised for a time in the United States, but he has been at Liverpool for the last eighteen or twenty years and has there been held in great respect by his profession and the public. He was an accomplished linguist, and his taste was for literature in all its branches. He was known to intimate friends to have some cardiac affection, and of this he died.

Dr. W. J. Martin of Dublin died on the 4th inst., of cardiac failure. He had been out of health some time, but was able to perform all his regular work up to the day preceding his death. He had been a traveler in both hemispheres and was a most interesting conversationalist. He was Inspector of Anatomy and Surgeon to the Lunatic Asylum.

Dr. Oscar Woods, Superintendent of Cork Asylum and a former president of the Medico-Psychological Association, died on the 2nd inst., aged 58. He was a T.C.D. graduate in Arts and Medicine (1868-9).

Dr. R. J. J. Macdonald, who was killed by Chinese pirates while he was attending to the wounds of the captain of the boat which they attacked, was a medical missionary who had worked in China for above twenty years. He was an Edinburgh M.D. In the course of his mission he had often encountered great danger from pirates and others, but nothing could deter him from the effort to benefit the Chinese.

Dr. John Hudson died on the 6th inst., aged 88. He was at one time medical officer of the *Dreadnought* hospital ship. He qualified in 1841, took M.B. (Lond.) the next year, and M.D. in 1846.

OUR LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

THE ILLNESS OF THE SULTAN ABDUL HAMID—THE EXPORTATION OF ROSE ESSENCE—A DECISION OF THE BOARD OF HEALTH.

CONSTANTINOPLE, August 16, 1906.

For the first time during his long reign, the Sultan Abdul Hamid II. (he ascended the throne of the Ottoman padishahs in 1878) was prevented by illness of a serious character from attending, on Friday last, the religious military ceremony of the so-called Selamlik. All sorts of alarming rumors were circulating throughout the city. It was even affirmed that the Sultan was dead. Some said he was poisoned. In one of the German newspapers appeared the sensational news that he fell a victim of a palace revolution. Of course there was no true word in all these startling rumors. Unfortunately, it is very difficult, and sometimes quite impossible, to gather trustworthy information concerning things of Yildiz-Kiosk (Star-Kiosk, the present residence of the Ottoman monarch), and especially of the Padishah himself, whose person and actions are always kept in most profound secrecy. The mist of densest mystery pervades the whole atmosphere where the sacred individual of the Moslem Khalif moves and has his being. No bulletins of any kind are ever issued, and nobody is allowed so much as to ask how his Islam Majesty is getting on. He is always supposed to be beyond the limits of human possibilities, and usual ailments of simple mortals are supposed never to approach and profane him. The alarming news concerning his present illness is, of course, due to this secrecy. Angina pectoris, Bright's disease, typhoid fever, and what not were affirmed to be the cause of his trouble. Now the real state of things is as follows, so far as it has been possible to ascertain from reliable sources: Abdul Hamid is suffering from a very chronic affection of the prostate gland. This affection has lasted for over ten years. In the beginning of it the body-physicians of the Padishah, together with a prominent German surgeon, had decided that operative interference was necessary. All the required preparations were made at that time to perform this operation. At the last moment, however, Abdul Hamid suddenly refused to submit himself to it. The trouble consequently went on, relieved from time to time by different palliative measures, until it reached the present serious stage. The Padishah is now suffering from all the train of symptoms referable to and connected with chronic prostatitis. There is the irritability of the bladder, which is said to be enormously distended; there is great difficulty in micturition; there is cystitis as well as some digestive trouble. There is reason to believe also that lately pyelonephritis has set in. The distinguished

German surgeon, Dr. Bergmann of the Berlin University, has been telegraphically summoned to come as speedily as possible to Constantinople in order to attend the Sultan, who is said to suffer great pains, being quite unable to pass his urine. It is possible that he contracted a "chill" during his usual promenades in the extensive gardens of the Yildiz-Kiosk, which chill seriously accentuated the chronic trouble. It is asserted that the introduction of the catheter for the purpose of drawing off the urine causes him untold sufferings. Whether he will, at last, submit himself to operative treatment is very doubtful. He shrinks from the lancet, as well as from anything suggestive of drastic interference. Besides, he was never a great believer in the efficacy of medical or surgical treatment. Medicine and surgery never appealed to him as being real sciences working on strict principles. Being an old-fashioned Moslem, pious, devout, and bigoted, he always most readily takes recourse, when he is feeling unwell, to all sorts of house remedies. Frequently also he is fond of consulting the occult lore of Arab medical wisdom. This time, however, the trouble was too serious and would not yield to any domestic remedies or Arab talismans. Thus Dr. Bergmann had to be asked to come. To-day, for the first time, a notice of an official kind, something like a bulletin, appeared in all the local newspapers, Turkish, Greek, Armenian, English, and French. This notice is very characteristic of the desire pervading the court circles to conceal matters or to represent them in a false light. It runs thus: "It is officially notified that His Imperial Majesty the Sultan was suffering from a slight cold on Friday last and that consequently the ceremony of the Selamlik did not take place. The Lord be praised, His Imperial Majesty has completely recovered his health to-day." This "complete recovery" is, of course, fictitious. The body-physician of Abdul Hamid, Marshall Dr. Nefiz Pasha, has frequent recourse to injections of morphine in order to lessen the Sultan's intolerable pains. It is possible that he will be able, with great difficulty and effort, to attend the next Selamlik. Of complete recovery, however, there could be no question, taking in view, especially, the fact that Abdul Hamid is old (he is approaching seventy) and that his general health, apart from the present trouble, has been undermined by all sorts of worries, fears, political complications, etc. A friend of mine who has access to Yildiz-Kiosk and who knows the affairs concerning the Sultan very well, tells me that the latter looks at present a mere wreck, unable to walk without support. The question of a successor to the Ottoman throne is beginning very seriously to occupy the minds of the highest state officials and courtiers. Let us trust that matters will take a regular peaceful course, without any sanguine revolutions, should another Khalif have to occupy the throne of the Osman padishahs. The United States Minister, Mr. Leishman, as well as all the other representatives of foreign Powers, received Saturday last the following official communication from the Chief Chamberlain of Abdul Hamid: "His Imperial Majesty the Sultan, my August Sovereign, greatly appreciated your Excellency's good wishes conveyed through your first dragoman. By order of my August Master I have the pleasure to announce to your Excellency that His Imperial Majesty has completely recovered. His Majesty looks forward to shortly receiving your Excellency and verbally expressing his satisfaction."

The *Courier de Sofia*, a business periodical published in the capital of Bulgaria, gives very interesting details concerning the exportation of rose essence from that principality. Bulgaria has sent out to foreign markets, from 1886 to the end of 1895, *i.e.* during a period of ten years, an average of 3,011 kilograms of rose essence yearly, of the annual average value of 1,639,754 francs, at 544.5 francs per kilogram. From 1889 to 1905 the exportation rose to 4,150 kilograms per year, amounting to the annual average of 2,749,926 francs, at 662.6 francs per kilogram. From these figures it is seen that the rose essence exportation from Bulgaria has very considerably increased in the latter years. The rose essence is exported to almost every country of the globe. Not all the markets, however, are regular, and the business is not proportionate to the increase of the production. For the present the markets of England, Austria, Germany, Italy, Russia, Turkey, France, and the United States of America are the most stable. The regular exportation to the last-named country dates only from the year 1897, when but 12 kilograms was exported. In 1905, however, the exportation increased to 1,641 kilograms, or 30.8 per cent., or, in other words, America occupies in 1905 the first place. The total export in 1905 has risen to 5,316 kilograms, to the value of 3,712,388 francs.

By decision of the Board of Health, arrivals from Suez are to be subjected to medical inspection and disinfection, and to the measures contained in the Circular 180 regarding the destruction of rats and vermin on board the steamers. The decision of the board applies to all vessels leaving Suez on and after July 27 old style (August 9).

Progress of Medical Science.

Boston Medical and Surgical Journal, August 23, 1906.

Gastric Ulcer and Cancer.—Christopher Graham states that in view of the fact that ulcer may, and often does, have a latent period of years and that cancers with short histories frequently show old ulcer base, it seems just to assume that many, if not all, rapidly developing gastric cancers have found a fertile soil on a previously developed ulcer area. After describing the symptoms of the four stages in gastric ulcer development—when cancer did develop they would expect it to do so in the third or fourth stage—he said that in his series of cases the males and females ran in proportion of 4 to 1 and ranged in age from 29 to 76, the average being a little over 50. About three-fourths presented themselves for the amelioration of symptoms that had been present for one year or less. In the series of 1905 pain was rather constant. Vomiting was not recorded n 11 histories, 3 had no vomiting, while 68 complained of it. In 42 the lesion was situated at the pylorus or lesser curvature, in 3 at the cardia. Of the whole number operated upon, 67 had test meals. Tumor was present 27 times, doubtful in 3 more. Dilatation was present in 54 and obstruction in 36. In 32 free hydrochloric acid was present, combined in 32, lactic acid in 42, fatty acids in 19, both hydrochloric and lactic in 13. Blood was often found. Figures presented seemed to emphasize that short histories and ulcer as the old lesion on which cancer is grafted are not incompatible, as some argue, and that ulcer is the great and fertile soil of cancer.

New York Medical Journal, August 25, 1906.

Sternomastoid Breathing.—Robert H. Chase makes a study of sternomastoid breathing in the dying state, basing his records on 1,500 personally observed cases. At least 90 per cent. of these persons died in an unconscious state. Not very long before death supervenes the head of the patient moves up and down in a rocking fashion, synchronously with the breathing; this action, a veritable death's call, is brought about by the strong contraction of the sternomastoid muscles in an effort to facilitate breathing. The duration of sternomastoid breathing varies from one minute to seven hours, the median length of time that it lasted before death was twenty minutes. He concludes his paper by stating that sternomastoid breathing is a reliable sign of approaching death, and one which may serve the purpose of the physician in forming an estimate of the length of time the patient may live, without depending on signs of less value; that its onset indicates that death is probably very near at hand, generally within half an hour; that it is a definite symptom on which the physician may predicate his instructions or advice; that it is a sign to mark the time when the family may be summoned to the bedside.

A Contribution to the Study of the Spanemic Heart.—Charles Ross Jackson says that a spanemic heart is one which, by reason of deficient nutrition of its muscle, is dilated or dilatable. He considers three varieties: 1. The heart insufficiently nourished on account of general anemia. 2. The heart insufficiently nourished because of more or less persistent vasomotor failure, the blood being normal. 3. The insufficiently nourished heart from a combination of blood disease and vasomotor instability. There is a recital of cases to illustrate each of these varieties. The treatment of the first class demands the free administration of iron, and, whether dilatation be present or not, much good follows a thorough control of the heart by digitalis or strophanthus during the anemic state. Arsenic is of value. The treatment of the second variety calls not only for digitalis, but also for direct vasoconstrictors. Ergot was of value and cannabis indica seemed to him to give excellent results. The third form calls for cardiac and anemic treatment, and for direct vasoconstrictors as well. His endeavor was to hold the heart at about 70 and to dose accordingly.

Strychnine as a Remedy in Pulmonary Tuberculosis.—W. P. Milroy says that ten years ago William Pepper called attention to the value of strychnine in pulmonary tuberculosis, and he has used this remedy with gratifying results repeatedly. Four doses should be given during the twenty-four hours, beginning in an adult with 1-30 grain at each dose. At the end of each period of five days he adds 1-30 grain more to one of the doses until 2-30 grain is given four times daily. Above this amount the increase is by 1-60 grain until the physiological limit is reached, when the dose should be diminished by about 1-4 and then gradually increased again. The great benefit accrues only

when the maximum dose is taken. Strychnine secures so vigorous an awakening of the sluggish cell life as once more to establish the broken defense against the tuberculous invasion. He is of the opinion that strychnine should be administered in pulmonary tuberculosis whenever the fresh-air treatment is not available, and he knows of no reason why it might not be used to advantage in conjunction with the fresh-air treatment.

Journal of the American Medical Association, September 1, 1906.

The Afferent Nerves of the Skin.—M. von Frey remarks that our insight into the distribution of the afferent nerve fibers is very incomplete. In dealing with sensory disturbances in man after injury to cutaneous nerves, the first thing to be considered is what kind of sensations belong to the normal skin and to the underlying tissues. He concludes that the nerve supply to the skin can be considered a fourfold one. The surface of the skin is divided into a very large number of minute areas, representing the fields of distribution of the nerve fibers serving the sensations of touch, pain, heat, and cold. According to a rough estimate on the trunk and limbs, there are about 30,000 warm spots, 250,000 cold spots, and half a million touch spots. Reliable determinations as to the number of pain spots are lacking; it is more difficult to mark out exactly the localities of maximum sensibility to pain.

Individual Health Inspection.—L. F. Bishop advocates the practice of health inspection of individuals generally, to detect disease or defects that may endanger health before it becomes difficult to remedy. Hundreds of lives, he says, are lost, and thousands of days of disability, because of the lack of such foreknowledge. The examination should be thorough, complete, and necessarily technical, in its nature, demanding special skill, and for this reason he suggests the organization of cooperative clinical laboratories for this purpose, where men trained in the technicalities of chemical and microscopical research can do the work for the actual practitioners. It should be a place where the older physicians in practice can meet and discuss the significance of things with their fellows, and thus make clinical pathology a practical matter. He believes that patients will learn to submit to this system in larger numbers as it becomes better known, and the public can be educated to employ its physicians to watch the health of the individual in the same way as they are expected to watch over the health of the community.

Sleep.—Norman Bridge considers that the teaching as to the necessity of a large amount of sleep is often erroneous and leads to overdrugging by powerful and somewhat dangerous medicines. He lays much of the evil to the mental attitude of the sufferer. The horrors of insomnia are but slightly due to want of sleep and very much due to the fear of sleeplessness with which the patients are nearly always afflicted. If they could go to bed and feel that they did not want to go to sleep, or did not care whether they slept or not, sleep would probably come before they were aware of it, and last the night through. The notion that we go to bed for the purpose of sleeping is a one-sided one. It is bodily rest that we require as much as brain rest, and this bodily rest need not be accompanied with sleep all the time. Even children do not need so much sleep as has been supposed. We should put ourselves in a position of rest, which of itself, physiologically, induces sleep. We should avoid the irritations, noises, bad air, cold feet, overloaded bowels, etc., which tend to keep us awake, and to prevent proper physical rest, and then sleep comes of itself usually, and almost always in sufficient quantity. Five or six hours may be as good as eight for some people.

The Surgical Treatment of Exophthalmic Goiter.—F. J. Shepherd maintains that in a certain proportion of cures, operative measures are curative, or lead to decided improvement. The probable cause is hyperactivity of the thyroid, but the part played by the thymus and other causes in this disease complex cannot be entirely ignored. Early operation is safest, and the class of cases most likely to be benefited are not the most severe ones, but those in which the gland is more enlarged on one side than on the other, with more definite tumor formation, and in which the gland is not excessively vascular and the enlargement has preceded the symptoms by years. In those early cases of enlarged thyroid with mild symptoms, in which the gland is soft, vascular, and evenly enlarged throughout, the results of operation are usually good. In case of a large vascular thyroid, with symptoms of marked toxemia from thyroidism, operations should be avoided.

The Lancet, August 18, 1906.

The Sterilization of Tuberculous Sputum and Articles Infected by the Tubercle Bacillus.—Thomas Kirkland and Marcus S. Paterson state that until 1905 it was the custom to destroy all sputum in a cremator, while the cups were washed by hand and sterilized. The methods used were undesirable because of the risk of infection to those employed in sterilizing, the considerable expense entailed in keeping the cremator in repair, and the cost of special handkerchiefs. Their experiments upon the sterilization of sputum seem to establish the fact that articles infected with the tubercle bacillus might be rendered sterile at a temperature of 200° F. From this it follows that any article infected with the tubercle bacillus might with certainty be rendered sterile by boiling it in water for half an hour under atmospheric pressure.

Observations on the Life History of Leucocytes.—C. E. Walker states that it has been elsewhere recorded that one of the earliest phenomena in the occurrence of malignant growths is the invasion of the tissue cells by leucocytes with the subsequent common division of both nuclei, and this produces a race of hybrid cells, half tissue cell, half leucocytes. It has also been recorded that the cells of malignant growths reduce in a similar manner to the cells of reproductive tissue. All the forms of cell division seen in malignant tissue are also seen in normal leucocytic tissue, and both leucocytes and malignant tissue are out of coordination with the true soma. According to observations the hybrid cells act just as would be expected and possess the characteristics, to a certain extent, of both their ancestors.

Frictional Electricity a Factor in Caisson Disease.—George W. F. Macnoughton says that caisson disease may occur rarely in the caisson, not so rarely immediately on quitting, usually some hours afterward, and not uncommonly for two or three days after the exposure to the compression. The work of a caissonier causes a repletion of the visceral veins and those of the cerebrospinal axis. The spinal column and its contents have thin-walled venules, inclosed by the inelastic perilymphatics, and are especially liable to become overdistended through the increased tension, creating local pressure and a local rise of acidity, thus stimulating the discharge of energy. These workers accumulate upon the body surface electricity which reaches the nerve centers, throwing the nerve cells into a state of excessive activity. The electricity of the caisson atmosphere is hydroelectric in origin, and the means at present in vogue of compressing and conducting air into the workings is an enlarged continuous performance of the Armstrong-Faraday experiment, with moist air instead of steam. He believes that the air of the intake should be absolutely dry, which might be arranged through heated tubes arranged in a furnace like those of locomotive boilers or one of the heat economizers in general use. There is a great similarity between the symptoms of a nonfatal lightning stroke and an attack of caisson disease, while the return shock of lightning is physically comparable to the changes which follow a too rapid decompression after long exposure in a caisson atmosphere.

Observations on the Action of Strontium Salts on the Coagulability of the Blood.—J. B. Nias concludes from his experiments that it is clearly established that the lactates of both strontium and magnesium in doses of from one to two grams are serviceable substitutes for the salts of calcium when the latter are not absorbed from the alimentary canal, thus enabling us to dispense with the dangerous practice of hypodermic injection which his experience does not show any advantage in speediness of action.

British Medical Journal, August 18, 1906.

Direct Examination of the Esophagus and Upper Air Passages.—D. R. Paterson says that to Mackenzie belongs the credit of being the first to record the extraction of a foreign body by the direct method, but this procedure did not come into general employment until 1881, when improved models were introduced by Mikulicz. In the direct examination of the esophagus Rosenheim's tubes are the most convenient, with the patient sitting on a low stool with the head hyperextended and steadied by an assistant. Esophagoscopy he claims to be the safest and most certain method in the extraction of foreign bodies, and all other methods by bougie or coin catcher, or by pushing the body into the stomach, should be avoided. The cases detailed by

him afford evidences of this. From the evidence produced it appears abundantly clear that the direct examination of the air passages is a method of the greatest utility and especially welcome in that group of cases which has always been so difficult and has yielded not a few tragedies, foreign bodies in the air passages, and it is earnestly hoped that the time has come when workers will recognize its enormous advantages.

Human and Bovine Tuberculosis.—Nathan Raw concludes that human and bovine tuberculosis are distinct varieties of disease, but that the human body is susceptible to both, and especially to bovine tuberculosis in the milk-drinking period of life. His opinion is based almost exclusively on clinical and pathological evidence.

A Case of Sudden Death Possibly Due to Vague Inhibition.—E. D. Telford reports such a case following an operation on chronic tuberculous cervical glands. At autopsy, at the level of the first dorsal vertebra, the right vagus disappeared into an elongated mass the size of a large filbert, formed by the fusion of several enlarged and tuberculous glands. The nerve was swollen for one inch before its entry into the mass, while at the point of entry it was actually constricted as definitely and sharply as if it had been encircled with a ligature. Brouardel quotes a case of sudden death in which the post-mortem findings offer a striking parallel to those observed in this case. On the other hand, the vagus has frequently been injured or divided in surgical work and did not appear to produce any noteworthy results.

Berliner klinische Wochenschrift, August 13, 1906.

Polyarthritis Chronica Deformans.—H. Curschmann refers to the tendency which exists to make an indiscriminate use of the terms chronic rheumatism, chronic arthritis, arthritis deformans and gout, and believes that it is possible to differentiate these various conditions more closely. Under the title noted he describes a disease which involves all the joints, beginning with the smaller ones, which exists as a clinical entity. He has studied the various stages of this disease by the aid of the *x*-rays and bases his observations on a series of 167 cases. The process begins in the joint capsules and ligaments rather than in the bones or cartilages, and the patients give the impression, as they often have fever, of being the subjects of an attack of acute articular rheumatism. The fingers and toes, however, are the joints usually involved at this time, and these are infiltrated and tender. Motion is not greatly interfered with, but there soon occurs a progressive atrophy of the muscles of the hand. There is more or less displacement of the bones of the joints, owing most probably to the changes in the capsule and ligaments. The cartilages next become involved, and then joint crepitus can be elicited. In the course of several years the larger joints become involved and their mobility retarded, even the jaws being included. The disease may begin in early life, but the author does not give any details as to its etiology. It is very apt to be associated with a variety of chronic skin diseases, such as vertigo, ichthyosis, psoriasis, and eczema.

Poisoning by Meat and Paratyphoid.—H. Trautmann has been one of a number of investigators who pointed to the apparent resemblance between the bacilli of paratyphoid and those associated with poisoned meat. The writer's contention, based on clinical and experimental observations, is that poisoning due to meat is an acute and paratyphoid, a subacute manifestation of an etiologically identical infectious disease. In the former the toxemia occupies the foreground of the clinical picture; in the latter the general symptom complex is that of an infectious disease. In the first the virus is already effective when introduced into the body; in the other the preliminary stage is gone through in the body itself.

Muenchener medizinische Wochenschrift, August 14, 1906.

Notes on the Transmission of Typhoid in an Asylum for the Insane.—Nieter and Liefmann report on the conditions in an institution containing nine hundred female insane patients, in which typhoid had been endemic for a number of years and persisted in spite of the efforts directed toward an improvement in the water supply and general hygienic conditions. Careful and continued examination of the stools of a large number of cases showed that certain patients afflicted with an ordinary acute dysentery also disclosed numerous typhoid bacilli in addition to the bacillus of Flexner. It seems very likely that these patients who merely had an ordinary diarrhea without typhoid symptoms served as the means of transmitting the true typhoid to others. As soon as these patients were isolated the epidemic ceased.

The Relation of Tetanus to the Female Sexual Organs.—E. Gross refers to the statement made by a number of writers, that the tetanic convulsion is brought about by the contractions of the uterus, and in support of the same reports cases in which the spasms were set free by contractions in the puerperal as well as in the nonpregnant uterus. In one the convulsions followed closely after curettage. The size of the thyroid also seems to have an important bearing on the question, but the exact relation must be determined by further experiment.

The Etiology of Prurigo.—Steiner and Vorner report a case in a woman of 26 who had never been previously affected with the disease but who suddenly developed an attack during a colitis. The latter was cured, but the skin affection persisted. The close resemblance between urticaria and prurigo has often been noted, and as the former is believed to be due to an irritation proceeding from the intestinal mucosa, the writers suggest that the prurigo may also be due to the same cause. In many cases of catarrhal colitis the skin eruption may not be noticed while the intestinal condition is being treated, but its reappearance at a later time will usually have been preceded by an attack during a previous colitis. The condition is very resistant to treatment.

Deutsche medizinische Wochenschrift, August 16, 1906.

The Treatment of Chronic Dysentery.—H. Meyer states that from our present knowledge of the subject we may divide this disease into four groups: the epidemic, the endemic amebic, the mild amebic enteritis, and diarrheas due to coccidia and infusoria. He claims that there are many cases in which the ameba is the etiological factor, although the patient has never been in the tropics, and all obscure chronic cases should be examined for this protozoon. Even when the amebæ are not found in the stools it is advisable to treat the patient with ipecac and iodoform enemas, presupposing, of course, that there is no intestinal tuberculosis, achylia gastrica, or other form of dyspepsia present. The writer places great reliance upon the ipecac and iodoform. The latter is given as a rectal injection, 5 gm. of iodoform in 1,000 c.c. of mucilage of gum Arabic, with the patient in the knee-chest position, and then massaged as far as possible up into the colon. This is left in the gut for ten minutes and then as much as possible washed out with plain water enemas. The author reports three cases in which this treatment was used with success. The ipecac is used in the form of emetin and cephalein, about one and a half grams being administered daily.

The Treatment of Basedow's Disease with the X-Rays.—J. Slodowski reports a case in which the patient afflicted with this disease gained 13.3 kilos in a period of sixteen weeks, during which she had been treated with the Roentgen rays. The abnormal perspiration was also stopped and the general nervous condition was improved, but the other features of the disease remained unchanged. The improvement is ascribed entirely to the *x*-rays and was almost immediate, and remained so for a period of six months, up to the time of the report. The most marked effect seemed to be exerted on the nutrition and secondarily on the nervous symptoms. The tremors, the exophthalmos, and the frequency of the pulse did not seem to be affected, although it may be that the treatment was not kept up for a sufficient length of time.

French and Italian Journals.

Diverse Forms of Anemia in Chronic Tuberculosis.—Marcel Labbé thinks that it is necessary to consider the total quantity of blood and the proportion of its elements in order to appreciate the anemia of tuberculosis patients. He distinguishes three different forms of anemia in chronic patients: 1. Anemia with yellow skin is the type most common when fever is present. The pallor of the skin corresponds to the diminution in the number of red blood cells and the quantity of hemoglobin, the diminution in the globular value, and the weakness of arterial tension. This anemia is due at the time to the diminution in the quantity of blood and to the globular destruction. 2. Anemia without yellow skin appears rather in patients with no fever. The number of red blood cells is greatly diminished, the quantity of hemoglobin lowered, the globular value elevated, the arterial pressure strong. In these cases the quantity of blood is not diminished and the globular destruction is at a minimum. 3. Yellow skin without anemia is rare. It is consecutive to a slow denutrition. The

proportion of red blood cells and of hemoglobin is normal, but the arterial pressure is lowered. The color is pale. There is a diminution in the amount of blood, but the composition of this fluid is normal.—*La Presse Médicale,* July 4, 1906.

Supernumerary Teeth and the Roentgen Ray.—S. Dunogier, from his investigations in this subject, concludes that the *x*-ray offers a sure means of detecting supernumerary teeth when these teeth appear before the permanent teeth of the same region. By this means the physician can differentiate normal teeth which are abnormal in direction of growth from supernumerary teeth. The *x*-ray also reveals through the thickness of the maxillary process the permanent teeth in process of development. Their form, their direction of growth, and their distance from the border of the gum can be observed. By employing the *x*-ray at regular intervals it can be seen if the supernumerary teeth form an obstacle to the development of the permanent teeth. The most propitious time for intervention may be learned in this way.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux,* June 24, 1906.

Treatment of Tumors by Glycolytic and Pancreatic Ferments.—M. R. Odier has made various researches in relation to the treatment of tumors by glycolytic and pancreatic ferments. He noted in certain pathological conditions, especially in malignant neoplasms, that there was an increase in the amount of glucose in the tissues. He believes that the character of a malignant tumor depends not alone upon the tumor itself, but upon the diathesis of the patient. This is why he thinks that the diathesis ought to be modified. The animals which have served for his experiments were of various kinds, horses, sheep, dogs, and domestic rats. The tumors were sarcomata, carcinomata, papillomata, and one adenoma. This investigator demonstrated the constant diminution of glycolytic and pancreatic ferments in these cases. The treatment consisted of injections charged with the ferments in question. The author has kept under observation five dogs, one rat, and one horse, from four years to a year and seven months. In these seven animals the position of the tumors has remained stationary. The volume of the tumors decreased to a condition bordering on the normal following the treatment by daily injections.—*La Presse Médicale,* June 30, 1906.

Treatment of Ingrowing Nail.—Drucbert, in his hints on the prophylactic treatment of this affection, states that thick and very convex nails have a natural tendency to penetrate the flesh. Flat, small nails covering large fleshy toes, when the tissues are not very resistant, are apt to be overgrown by the skin. He advises saline baths, as well as alum and tannin, for tender tissues. The greatest care in the toilet of the feet should be taken in cases showing a predisposition to ingrowing nail. Inflammation should be carefully watched for and kept in check. Curative treatment depends upon the degree of inflammation. Long walks and standing on the feet should be avoided. The application of antiseptics, such as sublimate, which will reduce the inflammation and prevent further trouble, is indicated. Dressings repeated several times daily will help to keep the trouble in check. A bit of dressing covered with vaselin may be gently forced under the nail. In more severe cases radical treatment is in order.—*Journal de Médecine de Paris,* June 24, 1906.

Pathology and Treatment of Multiple Hemorrhagic Sarcoma of the Skin.—Francesco Radeli states that the idiopathic sarcoma of Kaposi is an angioendothelioma originating in the blood-vessels. He has used the Finsen light in the treatment of these growths and has made histological examination of the tissue resulting after the treatment. His conclusions are that there are in the foci of growth of Kaposi's disease formations of an endothelial nature originating from the endothelium of the blood-vessels. The application of the Finsen rays produces a resolution of the cutaneous new formations. This resolution takes place by the acceleration of the spontaneous process of resolution which is going on in the growths, that is, by proliferation of the connective tissue surrounding the new growths and by secondary atrophy. In the cicatrix produced by the Finsen rays there is a large number of elastic fibers, which explains the distensibility of the cicatrices formed.—*Le Sperimentale,* Vol LX. No. 3.

Lesions Produced by the Acid-Resisting Bacteria.—Michele d'Amore calls attention to the fact that the acid-resisting bacteria produce tubercles in the tissues that are similar to those produced by the Koch bacilli, but that are not identical with them. He has conducted experiments by inoculating these bacteria and made careful histological examinations of the resulting tubercles, and gives the conclusions at which he has arrived. There is a great similarity in structure between the tubercles of the Koch bacillus and those under discussion, but there are certain differences that separate them in structure. The acid-resisting bacteria are only slightly virulent to animals. The differences in structure are more marked when fats are injected with the bacteria. Artificial infection does not produce any progressive disease or proliferation in the tissues. There is a tendency to caseation of the tubercles, but there is no dissemination into the surrounding tissues. There are structural differences in the tubercles, such as differences in the giant cells and the epithelioid cells. The author believes that, taking into account the structural differences and the differences in the course of the affection, there need be no difficulty in arriving at a diagnosis.—*Giornale Internazionale delle Scienze Mediche,* June, 1906.

Metabolism in Pulmonary Tuberculosis.—G. Vannini and M. Collina have made experiments to determine the changes in metabolism that go on in tuberculous subjects. Consumption is a disease in which the nutritive balance is affected so that the patient lives on his own tissues. It is desirable to know what part in these changes is taken by the deficiency of food eaten and what part by the intoxication produced by the disease. The conclusions arrived at by the authors are these: Absorption in those patients that have no especial disturbances of the alimentary canal goes on normally, but the loss of nitrogen through the feces is increased, so that finally there comes about a state of hyponitrogenism. The fats of the feces contain more glycerides and less ordinary fats. In apyretic tuberculosis there is an equilibrium or retention of nitrogen, while when there is fever the albumin of the organism is destroyed. As to the nitrogenous substances of the urine, there is a diminution in the amount of nitrogen in urea and a slight increase of nitrogen in ammonia eliminated. Uric acid appears in normal quantity.—*Rivista Critica di Clinica Medica,* June 16 and 23, 1906.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE EYE AND NERVOUS SYSTEM. Their Diagnostic Relations. By Various Authors. Edited by WM. CAMPBELL POSEY, A.B., M.D., Professor of Ophthalmology in the Philadelphia Polyclinic; Surgeon to the Wills Eye Hospital, etc., and WILLIAM G. SPILLER, M.D., Professor of Neuro-Pathology and Associate Professor of Neurology in the University of Pennsylvania; Clinical Professor of Nervous Diseases in the Woman's Medical College of Pennsylvania, etc. Illustrated. Philadelphia and London: J. B. Lippincott Company.

THE borderland between ophthalmology and neurology is a territory whose importance is universally recognized, yet until the appearance of the present volume no work written in English we believe has been devoted to just this field. The neurologist is accustomed to seek almost daily counsel of his ophthalmological confrère, and the latter is constantly turning over patients to the specialists in nervous diseases, so that the presentation of a common form in which the subjects of interest to the two sets of observers are discussed by representatives of each camp is certainly highly desirable. The present volume is designed to furnish this consensus of opinions and the editors have been fortunate enough in their choice of collaborators to secure a list of names certain to stamp the volume with the seal of authoritativeness. In addition to articles by Drs. Posey and Spiller the work comprises chapters by Drs. C. W. Burr, F. X. Dercum, Alexander Duane, C. H. Frazier, Howard F. Hansell, William Hirsch, Edward Jackson, J. Hendrie Lloyd, Charles K. Mills, S. D. Risley, B. Sachs, Joseph Sailer, G. E. de Schweinitz, W. N. Souter, E. W. Taylor, G. L. Walton, John E. Weeks, T. H. Weisenburg, Casey A. Wood, and H. V. Würdeman. These separate monographs form a harmonious mosaic in which there is a sense of well planned continuity, and what repetition does occur is not undesirable since it reflects the points of view of the two branches represented by the writers. The book is essentially a work on special subjects designed to be of use to the practitioner, and the authors appear to have been careful to keep this end in view, for the manner of treatment is such as to enable the ordinary reader to derive the greatest possible benefit from it. The subject matter is divided into twenty-three chapters whose titles form too long a list for reproduction here, but it may be said that not only the theoretical considerations involved in the function of vision and its relation to the general nervous system are amply discussed, but also the various methods of testing for and investigating anatomical and functional disturbances are described at length. The last four chapters are among the most interesting in the book and are devoted to the psychological effects of operations on the eyes; the surgical treatment of intracranial lesions causing disturbances of vision; tremors, reflexes, and gaits; and degeneracy—these latter subjects especially indicating the breadth and scope of the book. The illustrations are numerous and form an interesting and valuable feature of what is a most instructive guide in a field that is usually approached by the practitioner with a certain degree of hesitation.

THE NATURE AND TREATMENT OF CANCER. Some Methods of Hypodermic Medication in the Treatment of Inoperable Cancer. By JOHN A. SHAW-MACKENZIE, M.D., Lond. Third Edition. Revised and Enlarged. New York: William Wood and Company, 1906.

THIS little work is devoted to a consideration of the treatment of cancer by means of the hypodermic injection of various substances—Chian turpentine, sodium oleate (soap), and trypsin, in conjunction with the internal administration of ox-gall. The theory upon which this treatment is based, or by which the results are explained, is that propounded by Mr. J. H. Webb of Melbourne that "cancer is uncontrolled cell-proliferation due to the deposition of cholesterin from the cell, either locally from injury or dependent on some chemical change in the liver secretion, associated with deficiency of the bile salts which normally hold cholesterin in solution." The argument is supported by numerous case reports. That cancer, malignant as is its usual course, is not the inevitably fatal disease it is generally supposed to be, is gradually becoming recognized. The not so very rare cases of spontaneous recovery in man and in mice and recovery under treatment by the *x*-ray, radium thuya, and the injection of various substances seem to show that it is possible to arrest the abnormal cell-growth, and raise the hope that we may yet discover in what this process of arrest consists. As an aid to this discovery the study of books of this sort is not to be despised, and with however much scepticism the study may be approached it is worth while making it; the seemingly most improbable theory may contain the spark which will furnish the light to illuminate this dark problem.

HEART DISEASE AND ANEURYSM OF THE AORTA. With Special Reference to Prognosis and Treatment. By SIR WILLIAM H. BROADBENT, Bart., K.C.V.O., M.D.Lond., F.R.S., D.Sc.Leeds, LL.D.Edin. and St. Andrews, F.R.C.P., Physician in Ordinary to H M. the King, and to H. R. H. the Prince of Wales; Commander de la Legion d'Honneur, etc., and JOHN F. H. BROADBENT, M.A., M.D., (Oxon.), F.R.C.P., Physician to Out-Patients, St. Mary's Hospital; Assistant Physician to the London Fever Hospital, etc. Fourth Edition. New York: William Wood and Company, 1906.

As was the case with the third edition of this well known treatise the preparation of the present revision has been entrusted to Dr. John F. H. Broadbent, son of the original author. The volume has been increased in size by the addition of chapters on the pulse, disease of the coronary arteries, bradycardia, and atheroma of the aorta which are by the junior author, while Sir William Broadbent has contributed new matter on angina pectoris and the functional affections of the heart. It is no longer necessary to expatiate on the value of the work or to point out its many features of excellence for it has long come to be regarded as one of the most authoritative expositions of the subject of heart disease and allied conditions, and is not likely soon to lose its eminent position. The additions to the present edition are well adapted to increase the utility of the work and in this instance to say that the book is one that should be in the hands of every practitioner really seems no exaggeration. The only criticism that suggests itself to the reviewer is that the subject of the clinical significance of variations in blood pressure is not accorded the attention it deserves in the light of modern investigations, and that the attitude assumed by the authors of discrediting the use of the sphygmomanometer is a step in the wrong direction. The statement in regard to the use of such instruments of precision: "nor is it essential for clinical purposes, as the finger can by practice be educated so that a trustworthy comparative estimate of the arterial tension can be made" is one that all clinicians, who have given themselves adequate opportunities for comparison between the blood pressure as "estimated" and as actually recorded by the manometer, will probably be inclined to consider ill advised, to say the least.

DAS HEUFIEBER; sein Wesen und sein Behandlung. Von Dr. ALFRED WOLFF-EISNER. Mit 10 Kurven und Abbildungen und 2 grossen Tabellen. Muenchen: J. F. Lehman's Verlag, 1906.

THE various chapter headings of this monograph are: History, theories of causation, clinical manifestations, differential diagnosis, relation of hay-fever to other maladies, tabulated summary of cases observed, therapy, including climate, hay-fever and temperament, organizations of hay-fever patients, and the relation of hay-fever to general medicine. Naturally considerable attention is given under the heading of therapy to the serum-treatment and to that by graminol, a congener of pollantin and a remedy with which we are in this country not at all familiar. The utility of the sera is recognized but they are not considered as likely to cure every case. A temperate tone runs through the book which, while containing nothing new, gives some interesting clinical experiences and will serve as an up-to-date exposition of the general hay-fever question.

PROGRESSIVE MEDICINE; A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia: Assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. June 1, 1906. Philadelphia and New York: Lea Brothers & Co., 1906.

THE current number of this valuable quarterly contains articles on Hernia, by W. B. Coley; Surgery of the Abdomen, exclusive of Hernia, by E. M. Foote; Gynecology, by J. G. Clark; Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Spleen, Thyroid Gland and Lymphatic System, by A. Stengel, and Ophthalmology, by E. Jackson. The contributions are all up to the high standard which we have learned to look for in this publication. The section on Gynecology includes a lengthy review of tumors of the uterus, both carcinoma and fibroid. Progressive Medicine is a very useful publication.

SECTION ON SURGERY.

Second Day—Wednesday, August 22.

The Operative Treatment of Irreducible Luxations of the Semilunar Cartilages.—Dr. JAMES BELL of Montreal discussed the free opening of the knee joint in irreducible luxations of the semilunar cartilages, of considerable importance, because they occurred usually in young men. Operative treatment was usually called for if complete restoration of function was to be had. When the knee joint was opened, not only would one find a displacement of these cartilages, but very often they would be torn, and at times direct manipulation could not restore the parts; often complete removal of them would be demanded. The semilunar cartilages could be often removed without materially interfering with the function of the joint. In eighteen months he had operated upon four patients, through a free anterior opening of the joint, a transpatellar incision. This opening gave free access and a full view of all parts. These four cases he briefly reported, and in each there was a restoration of flexion of 120 degrees or more. One of the advantages of the operation was that there was no weakening of the joint, because a bony union resulted. Other advantages were, greater ease and accuracy in the removal of the torn and dislocated cartilages, less manipulation, less risk of infection, better results, better control of all the stages of treatment, and convalescence was but slightly prolonged because of the necessity of obtaining bony union of the patella.

Dr. FRED LEM. GRASETT of Toronto emphasized the importance of a good-sized incision, and said that the results obtained by Dr. Bell should give every confidence in doing this operation.

Dr. F. M. MARLOW of Toronto asked Dr. Bell regarding the after-treatment of these cases, and said that his experience was limited to only two cases, both successful. His greatest difficulty was with the after-treatment.

Dr. EVANS of Huntersville, Ont., asked for more information regarding the technique of the operation.

Dr. JAMES BELL, in answer to Dr Evans' question, said that the incision was made through the lower one-half of the patella, and the joint so opened that the whole end of the tibia could be seen. If the joint was freely opened, anything to be done could be done with ease. In answer to Dr. Marlow, the said the only after-treatment was what was usual in fractures of the patella, keeping the joint fixed for five or six weeks, then moderately fixed for two or three weeks more, and then the patients passed from observation with directions only to avoid undue strain on the joint. There was no special after-treatment at all.

Intestinal Resection for Tuberculous Enteritis.—Dr. FRANCIS J. SHEPHERD of Montreal reported the case of a patient, aged 34 years, who was supposed to be suffering from appendicitis when admitted to the hospital. He had been a hard drinker, suffering from gastritis and nervous prostration. Twenty-four hours before seen he suffered extreme pain in the right iliac fossa; the pain radiated to the testicle and perineum. On admission there was intense pain in the median line below the umbilicus, a great deal of abdominal distention, and tenderness, temperature 103° F., pulse 124, and other signs which pointed without any doubt to the existence of a peritonitis. When the abdomen was opened stinking pus escaped. The omentum was thickened and reddened. The ileum was much inflamed, and there were areas of ulceration found. Pulling a coil of intestines out, a perforation was noted from which feces escaped. There was a series of ulcerations extending along the intestines for several feet. A distance of over five feet had to be traversed before healthy intestine could be found. Nearly the whole of the small intestines were studded with dark areas, indicating ulceration. The bowel was divided and the ends brought together with a Murphy's button, altogether over five feet being removed at this time. A rubber drain was inserted. The next day the patient was better, and one week after operation a fecal fistula developed, which closed spontaneously. Then followed almost a continuous improvement until the end of the second week, when a high temperature developed, with pain at the site of the wound, where was found escaping feces. A hole was found at the ileocecal junction. The patient was too weak to permit of further operative interference, and left the hospital after two months with a fecal fistula in his right loin. The Murphy button never passed. The patient died from exhaustion four months after the operation. A post-mortem examination was not obtainable. This case was a splendid example of how patients suffering from severe forms of tuberculosis of the intestines could stand operations.

Dr. JOHN B. MURPHY of Chicago said there was no condition to be met with in the peritoneal cavity that he feared more than multiple ulcerations of the intestines, with adhesions of the third type, which meant organic lesions. In the analysis of such cases he considered the differential diagnosis; there was no condition or lesion of the intestines so obscure in clinical manifestations as tuberculosis of the intestines. A patient might have tuberculosis involving the duodenum, the jejunum, and the ileum, and have no hemorrhage, and only a slight elevation of temperature. He recently saw a case of tuberculosis in which the entire intestinal tract was involved with but slight fever and no hemorrhages. Such cases were not rare. He called attention to the symptomatology of these cases, that is, the relation between the pain, the temperature, and hemorrhage. In appendicitis the attacks were different; here there was pain, elevation of temperature, nausea, vomiting, but an absence of blood from the alimentary tract, as shown by an examination of the feces. While there were pain, fever, and the appearance of blood, it was almost pathognomonic of a tubercolous lesion, and also that the lesion was in close proximity to some vessel of considerable size. With an extensive lesion as great as in Dr. Shepherd's case, with the patient almost depleted, one could get union after excision. This, though, could not always be secured in that class of cases where the peritoneum was involved as well. In those cases of extensive tuberculosis, particularly of the large intestine or lower portion of the ileum, he believed the operation of exclusion was the best operation until the tuberculous process was far repaired by rest, enabling the patient to tide over the immediate danger, and at the same time placing the patient in a condition for permanent repair of the tuberculous process.

Dr. WM. J. MAYO of Rochester, Minn., congratulated Dr. Shepherd upon the results he had obtained, and said that nothing more tried a surgeon than to open an abdomen and find such a condition present; it introduced a certain element of doubt as to what should be done. Tuberculosis of the intestines was undoubtedly a primary lesion, and it was more common than thought to be. Multiple points of tuberculosis, as in pulmonary tuberculosis, were comparatively common. He recently saw a patient who died, not from the lesion itself, but from some general infection which was caused by this local focus; at the postmortem the lung tissues and other portions of the body showed such gross lesions as to obscure the primary source in the intestines. He called attention to those forms in which there was a single ulcer, followed by stricture in the small intestines, a number of such cases having been reported. There was another class of cases thrown in with malignant disease, the so-called conglomerate tuberculosis, most common in the cecum in which the tumor developed. These were not at all rare. The majority of these came to operation, not as cases of tuberculosis, but as cases of

malignant disease, the real diagnosis not being made until the tissues were examined by a competent pathologist. These conglomerate cases came with a history of tumor, with repeated attacks of colic; sometimes the tumor existed for a number of months with certain obstructive phenomena, sometimes pointing to trouble with the appendix. They could be treated by excision and get well. In the operation it was wise not to attempt to restore the lumen of the intestine, but to remove the ileocecal junction and make an anastomosis in healthy tissue. The results of this procedure had been exceedingly good. When dealing with tuberculosis it was unfortunate that drainage had to be instituted, for, as a rule, it would be followed by fecal fistula. Now we could take enormous chances in suturing the abdomen completely and leaving Nature to do the best she could.

Dr. Ochsner of Chicago admired the surgical judgment as shown by Dr. Shepherd in the treatment of his case. It was important to his success that he did not fear to remove a considerable portion of the intestine, inserting his sutures in healthy tissues. The tendency in such cases was to do the slightest possible amount of injury; this resulted frequently in removing too small a portion of the diseased intestine, using a portion of the intestine for suturing when it was still somewhat suspicious.

Dr. John Stewart of Halifax referred to a case of tuberculosis of the intestine that resembled malignant disease, the diagnosis not being made with certainty until a microscopical examination had been made.

Dr. Arthur T. Cabot of Boston said that an etiological factor that should give us courage in attacking these cases was that usually they were primary in nature, and that the infection came from the bovine bacillus.

Dr. Shepherd of Montreal thanked his "American cousins" for their valuable discussion of his paper and their gentle criticisms.

The Treatment of Ascites Secondary to Chronic Hepatitis.—Mr. Sinclair White of Sheffield, Eng., read this paper. The term "cirrhosis of the liver" was restricted to the pathological changes usually described under the heading of "vascular cirrhosis." Its most obvious symptoms were hemorrhages from the alimentary tract and ascites. Biliary cirrhosis, whether due to infection of the bile passages or to other causes, was excluded. He said that ascitic effusion was largely passive, and directly due to interference with the passage of blood through the hepatic terminals of the portal vein. Proliferation, with subsequent contraction of the tissues forming the framework of the liver, was the principal cause of the obstruction; it might be supplemented by thrombosis of the portal vein and by defects of the general circulation. Fifty per cent. of the cases of cirrhosis of the liver ran their course to a fatal issue without the appearance of ascites. Its absence was explained by (1) the enlargement of the normal anastomotic vessels connecting the systemic and portal veins; (2) the development of new anastomoses in adhesions formed between the viscera drained by the portal vein and the abdominal walls. The value of drainage as an adjunct to operation was beyond dispute. Epiplopexy was contraindicated where any of the important viscera of the body were defective. It should in all cases be preceded by one or more tappings. Details of the operation varied, but omental fixation was the most important step. The pathological changes in the liver were permanent, and therefore incurable, but the ascitic phenomenon was capable of being arrested, and the life of the patient prolonged by the operation. His personal experience with epiplopexy comprised five cases, full particulars of which were given. Four of the patients were engaged in the liquor trade, and there was a definite history of alcoholism extending over a period of many years in each. In the fifth, the evidence of alcoholism was less obvious, but the liver showed typical hobnail changes. This patient died on the twelfth day after operation. The remaining four patients recovered and were cured of the ascitic condition.

Dr. John Stewart of Halifax confined his remarks to the pathological aspects of the question. The phenomenon of ascites might be considered to be due to one of three causes, hydremia, pressure, or thrombosis. Thrombosis, as a pathological cause, was of ideal simplicity, but of no great frequency. A case was reported by Monroe of Glasgow, in which the patient had been the subject of hematemesis. In that case there was a local obstruction due to thrombosis; in such cases a spontaneous cure might be expected. In cirrhosis of the liver, he asked what was the common cause of the effusion of fluid. The contraction in the neighborhood of the portal vein caused a backward pressure, with engorgement of the spleen and intestinal mucous membrane, leading to melena and gastric hemorrhages and accompanying ascites. The cause of the increase in the connective tissue was obscure. As Dr. White pointed out, there was much to be said against the toxemic theory. The whole subject of dropsical effusion was much obscured. In about fifty per cent. of the cases of cirrhosis, from whatever cause, there was no ascites at all. Sometimes the natural anastomosis was sufficient to prevent it. He thought that this was the result not only of a passive, but at times of an active condition, going on in the cells; not alone a filtering of fluid, but an active secretion as well. He emphasized the fact that cases of hepatic cirrhosis went on without the appearance of ascites. Again, patients had been tapped and it had been noted that there was a gradual lessening of the amount of fluid until at last there was no more effusion at all.

Mr. George Gray Turner of Newcastle-on-Tyne said that his part in the discussion could only be that of an emissary from Dr. Rutherford Morison, who shared with Dr. Drummond the credit of bringing the operation before the English-speaking world. Since September, 1894, there had been sixteen cases operated on at Newcastle-on-Tyne. Of this number five died within a few days, three from pneumonia, one from uremia, and one from cholemia. In no case was there any septic complication. None of these fatal cases was properly selected. One was complicated by nephritis, and in three the fixation was merely carried out as the last stage of an exploratory operation. Of the eleven that survived, five had subsequently died. Of the sixteen cases, only six fulfilled the conditions insisted on by Drummond and Morison, namely, that the patients selected for this method of treatment should have alcoholic cirrhosis with ascites, not complicated by cardiac, pulmonary, or renal lesions, and should have survived one or more tappings. Among these properly selected cases, three patients were alive and well, seven years and five months, twelve months and seven months after operation, and two lived in good health for five years and two years, respectively. The indications were (1) that the ascites was due to portal obstruction, and not to the toxemia that was so often present. Rapid wasting, slight jaundice, and early edema of the legs were bad signs. (2) The patient should have survived several tappings; this in itself might cure the condition and it might help to develop adhesions. It also might give an indication as to whether the patient would or would not survive the operation. (3) There ought to be no pulmonary, cardiac, or renal complications. Among the nonalcoholic cases, those due to syphilis had done badly, and any patient suspected of having this disease should not be subjected to operation until thoroughly treated with mercury and potassium iodide.

Dr. Wm. J. Mayo of Rochester, Minn., said that the cases selected for this operation should distinctly be those without other lesions. The good results only followed where there were no cardiac, pulmonary, or renalcomplications. At the present, any patient who showed extensive edema of feet and legs, or trouble with the heart, or albumin and casts indicating kidney complications, should not be operated upon. The mortality was high in such cases, or else there was practically no benefit to the patient. There was a class of cases not due to alcohol which was seen in the younger subjects, especially young women, in which for

some cause ascites appeared, and these cases could be relieved by operation. He believed this whole subject must be cleared up by surgical and experimental physiologists. To-day we did not know exactly what the real function of the liver was. Adami showed that in all probability its function was to destroy bacteria taken in the portal circulation and carried to the liver. This was important, as it helped to explain why surgery of the stomach was followed by pulmonary troubles so often. Again, an etiological relationship existed between the liver and the spleen. Again, in Banti's disease, there seemed to be some intimate association with liver conditions. He made a plea that the large universities, with their large amount of material at hand, should take up this study from the standpoint of surgical physiology, and determine if possible why such conditions should exist.

Dr. OCHSNER of Chicago said that there seemed to be a physiological balance in cases of ascites due to hepatic disease; one class of cases that seemed to be benefited by operation was on one side of the balance, while those that were not benefited were on the other side. Personally, he had not been able to determine these classes.

Mr. CHARLES JOHN BOND, F.R.C.S., of Leicester said he had been struck with the difficulty in some cases of satisfactorily bringing the liver in accurate adaptation to the abdominal wall.

Dr. CARSON of London referred to the difficulty of choosing proper cases for operation. He had two girls, aged 20 and 22 years respectively, with no alcoholic history, on whom good results were obtained by operation.

Sir WILLIAM HINGSTON of Montreal said that they were dealing with the results of disease, and not with the disease itself. Ascites might or might not be present; in either case there seemed to be no tendency towards death or towards recovery.

Mr. LYNN THOMAS of Cardiff reported a case operated on two years ago.

Dr. FRANCIS J. SHEPHERD of Montreal referred to the case of a woman with ascites, and in whom he found cirrhosis of the liver. He questioned her friends about any alcoholic history, and was informed that such was impossible, because she was the president of a Woman's Christian Temperance Union. He learned afterwards that she had been a free partaker of patent medicines containing much alcohol, and this caused a true alcoholic cirrhosis.

Sir HECTOR CLARE CAMERON of Glasgow remarked how far simple drainage was capable of producing effects which they desired from operation. Five or six years ago, after tapping ascites due to alcoholic cirrhosis, he noted that the little wound would not heal, and for three or four weeks the patient had his bedclothes saturated with the ascitic fluid. That patient recovered. He abstained from alcoholic habits and remained well for three years, when he suddenly died from some cardiac condition. Later the speaker was asked to deal with a case of ascites due to alcoholic cirrhosis. Remembering this former experience, drainage was instituted. The patient was fifty-six years old and had had twelve tappings, and always with a rapid reaccumulation of the fluid. He introduced a large cannula and trocar. This patient died two and a half years after this method of treatment was instituted. There had been no return of the ascites. He believed if this patient had abstained from alcohol he would have lived longer. He died from hepatic cirrhosis.

Dr. JOHN B. ROBERTS of Philadelphia took exception to the age limit being placed at sixty years for this operation. It seemed to him that if they operated under local anesthesia, making an incision through the rectus muscle, then introducing the covered finger, catching hold of the omentum and making two or three folds in it, and stitching it from the exterior, they would be able to operate upon cases when in very bad condition and with little operative risk. It was practically a subcutaneous operation.

Dr. GARROW of Montreal also discussed the paper.

The Surgery of Banti's Disease.—Dr. GEORGE ARMSTRONG of Montreal detailed a case, and referred to an unusual complication that occurred after the operation. Twelve hours after operation tetany developed, which persisted for some time. The eyes became fixed and staring and the muscles of the back rigid, and other signs of the condition were present. The patient finally recovered. He had been able to collect from the literature 32 cases, with 23 recoveries and 9 deaths, a mortality of 28 per cent. Following operation, the patients were practically restored to health, the leucocytosis and oligocytosis disappearing rapidly, as well as the pigmentation. The hematemesis present seemed to be due to obstruction to the flow of blood through the vasa brevia. The three following facts appeared to him to have become established in dealing with Banti's disease: (1) The disease was essentially, and without exception, a progressive one, and tended to destroy life; (2) no treatment, save removal of the spleen, was effective; (3) splenectomy was followed by improvement, even in advanced cases.

Dr. A. B. ATHERTON of Fredericton, N. B., discussed the paper.

SECTION ON MEDICINE.

Second Day—Wednesday, August 22.

The second day was taken up by a joint discussion with the section of physiology on overnutrition and undernutrition, with special reference to proteid metabolism.

Quantity of Food Required.—Prof. RUSSELL H. CHITTENDEN of New Haven, Conn., opened the discussion by questioning the present knowledge of the medical scientists with regard to the amount of fats and proteids needed to maintain health. It was easy, he said, to decide in conspicuous cases of undernutrition that enough food was not being taken. Just as with regard to similar cases of overfeeding, there was no doubt. The dietary standards of the civilized world, however, were all founded on certain old notions, and supposed to be ruled by instinct. Recent investigation seemed to show that these standards were nearly twice as high as were needed to enable man to maintain the balance of nutrition. The extra material, instead of doing good, very probably did harm. His own experiments showed that men could maintain nutritional equilibrium on about one half, or even less, the proteid material that was ordinarily consumed. These experiments had been carried on for months at a time, and concerned various classes of individuals. The present dietary standard was founded on habit, and instinct was relied on as the guide. This was interesting, but not scientific or convincing. No dietary standard could be suggested as feasible that did not maintain nitrogen equilibrium. In Dr. Chittenden's cases, however, not only there had been no loss of nitrogenous material, though one of the men had continued the diet for over four years, but all of those concerned in the experiment had found that they were in better health, suffered less from pains and aches of various kinds, and were less subject to muscular fatigue. All this had been accomplished without any increase in the carbohydrates consumed. In the soldiers furnished by the United States Government for experimental purposes, there was an actual increase in muscular strength. No deterioration in the blood was noted, though this was carefully looked for. It had been maintained that dogs perish when not given abundant proteid diet, yet in Dr. Chittenden's laboratory this had not proved to be so. One dog had lived on a low proteid diet for over a year on less than one half of this material supposed to be necessary to maintain life. Too much had been argued from dogs in this matter, and the analogy with man did not hold. There was more suffering in the world from overeating than from overdrinking. It had been suggested that excess of proteids increased vital resistance, but of this there was no proof.

Proteid Limitations.—Prof. HALLIBURTON of London said, in opening the discussion, that he fully agreed with Dr. Chittenden. Excess in meat eating was more harmful than excess in almost any other line. Experiments on animals were useful to point the way in questions of metabolism, but were not conclusive. If it was argued that the dog with a high proteid intake was a strong animal, it could be said in reply that so was the ox with a low proteid intake; each animal had, as it were, its own coefficient in this matter. Too much must not be concluded from laboratory observations. Lafcadio Hearn, in his book on Japan, had stated that much of the Japanese initiative and enterprise had developed shortly after they became a meat-eating instead of an exclusively vegetarian nation. The open-air treatment of tuberculosis included in most cases the taking of large amounts of food. This undoubtedly increased resistive vitality. The subject, therefore, was still open for discussion. Dr. Halliburton said that a great change had come over physiologists' knowledge in recent years with regard to the absorption of albumin. It was now known not to be absorbed as peptone, but rather as crystalline substances, resembling leucin and tyrosin. The albumin in human bodies was a new manufacture for the purpose. Nature always provided much more of this than was necessary. Leeds had pointed out that it was physiological to take a maximal amount of proteid material since the child provided with food by nature takes ten times the necessary quantity of this material. To take only just enough would be as foolish as to take food with the idea of producing a minimal amount of fecal refuse. It was known that a large amount of material must be consumed, and much of it eliminated, in order to carry on vital processes properly. The speaker said that our knowledge of metabolic processes was extremely lacking. It was possible that a large amount of proteid material must be consumed in order to secure certain crystalline substances that existed in such material in only very small quantities, yet these substances might be absolutely necessary for life. A ton of pitchblende must be taken to secure a few grains of radium, and many truck loads of blue earth for a few carats of diamonds. Perhaps some such reason as this would be found to account for the universal impression that men must consume so much more proteid material than the laboratory finds it necessary for them to have. In this a frank confession of ignorance and the assumption of a waiting attitude was the most important consideration.

Arguments for Proteid Consumption.—Dr. OTTO FOLIN of Waverley, Mass., said that the only arguments for large consumption of proteid material were founded on habit, and the old naive believe that cooked muscle was good to provide muscular energy. The diet of prize fighters and athletes was somehow supposed to help ordinary people to eat properly. In this physicians had been blind leaders of the blind. There existed a belief that, because successful nations were eaters of meat, therefore meat eating was important, and indeed indispensable for great vital activity. The argument from habit might be applied to such harmful things as alcohol, or tea, coffee, and tobacco. There was an instinct for meat eating, but quite as strong an instinct against manual labor. This was no argument that this instinct had to be followed. Science regarded such an opinion with suspicion at least, if not utter disdain.

Medical Aspects of Proteid Consumption.—Dr. R. HUTCHISON of London said that the problem of proteid consumption could not be solved by the physiologists alone, nor by physicians alone. The proteid minimum, that is, the small quantity that could be consumed with the maintenance of health, was a physiological ideal, while the proteid optimum, that is the amount of proteid material necessary to secure good health and strength and maintain them, was the physician's ideal. According to the French expression, in order to have enough one must have too much. The test of the proteid minimum could not come from laboratory experiments of a few months, but must be made by the observation of how men who had for years taken such limited quantities of proteid material stood acute disease. It had been said that meat proteid was harmful, but meat contained more than proteids, and was it the extras that were harmful? It had been said that the paroxysmal neuroses, such as megrim, had been cured by a lessened amount of fats, or by a lessened amount of proteids, or by a purin free diet. All of these could not be true, and it was extremely difficult to decide which was the efficient agent in such cures. Individual idiosyncrasy was extremely important. Metabolism was very different in different individuals. The physician must have the explanation for these individual differences before he could make dietary decisions for individual patients.

Laboratory Experience Fallacious.—Dr. LAPIQUE said that he had studied the rations of peoples all over the world, and had found that all of them were consuming more than would be approved according to Dr. Chittenden's conclusions. It was evident that the experiences of the laboratory were not to be taken seriously for practice, since nothing was known as to what parts of the proteid material consumed were most useful for nutritional purposes. Perhaps large quantities must be taken just to secure very small amounts of absolutely indispensable substances. The speaker considered that the time was not yet ripe for the physiologists to give conclusions to physicians in this matter, and further investigations were necessary.

East Indian Vegetarianism.—Dr. RAMARAT of Madras said that he represented hundreds of thousands of his fellow countrymen who had never touched meat or eggs or fish in any form. Even on this trip of ten thousand miles, he had given vegetarianism of this absolute kind a fair trial. He had not found it wanting. He had carried on a very active professional life for twenty-four years, and was sure that all the ordinary activities could be exercised without meat or the abundance of proteids consumed in the West. On the voyage he had seen many pitying glances cast at him because of his abstemiousness. He thought that the pity should be bestowed rather on those who bothered themselves with eating so much. The experiment of limited proteid diet had been carried on in India for many thousands of years by a people noted for its intelligence and for all of life's activities.

State of Knowledge of Nutrition.—Sir JAMES GRANT of Ottawa said that nothing was more important than this question of nutrition. There was no doubt that more people died from overfeeding than from the overconsumption of alcohol. At the age of seventy-five, he looked back over his professional career, and felt that most of the ills of mankind came from overfeeding. Knowledge of metabolic processes was most lacking. The nervous system in digestion was particularly ignored, though the very source of digestive impulse came from the nervous centers. He felt that this discussion, by disclosing present day ignorance, was bound to be of the greatest possible service to medicine.

Meat Stimulation.—Sir THOMAS BARLOW said that while Dr. Chittenden's researches were of the greatest possible service to medicine, they served but to emphasize certain phases of medical ignorance. Great additions to our knowledge were needed. Why was the flagging child improved so much by having meat put in its diet? Why was overfeeding in phthisis and neurasthenia so beneficial? It was evident that the observations in the laboratory had to be rationalized before they could be applied to the practical problems that came from the physician. Meantime, no subject was more important, and the medical world was under great obligations to Dr. Chittenden for having opened it up.

Dr. Chittenden said that he did not consider that the last word had been said as to proteid nutrition. A few years ago men were sure that much greater quantities were

needed; now a state of doubt had been created. That was the real object of bringing his experiments before the medical profession. The lack of knowledge on this subject had become very clear. The question had been raised whether many ills of humanity were not due to overeating because of false dietary standards. Now the thought has been fostered that a closer approximation to the minimum proteid requirement might be perhaps the best curative agent for such ills and save much suffering. Extractives in meat were not absolutely condemned, because perhaps they were stimulants. Proteids were not all the same; vegetable proteid was supposed to be the same as meat proteid, yet chemical analysis showed that it was three times as rich in glutaminic acid. Evidently the two substances were very different. The future alone could bring sure knowledge on these points.

Aminoacids and Metabolism.—Dr. Llewelys F. Barker of Baltimore said that all progress in medicine was looked for a few years ago from bacteriology; now the tide had turned and physiological chemistry had the vogue. Analysis of albumin had shown that the proteid molecules were very complex, yet were composed of chains of rather simple substances. These simple substances were mainly the aminoacids. A dozen or more of these were found in egg albumin. These constituted the basis of albuminous metabolism. The most familiar of them were leucin and tyrosin. Aminoacids occurred in two forms, the monoaminoacids and the diaminoacids. Curiously enough, these two substances were found to exist in the same proportion in such different proteid materials as the white meat of chicken, fish, the proteids of vegetables, and all other meat sources of proteids. Investigation had shown that each animal had its own specific albumin. The albumin of one differed from that of any other species. Each animal manufactured its own kind of albumin in its intestines. The same simpler crystalline materials were used by all of them, but the end results were quite different. In the blood the aminoacids were almost constant. Evidently the intestines made what was necessary, and took this work from the body tissues. Even exudates were digested into aminoacids before absorption. It looked as though the problem why sugar could be made from proteid materials was soon to be solved from the standpoint of the physiological chemist.

Treatment of Typhoid Fever.—Dr. F. T. Thistle of Toronto said that purgatives were the most important part of the treatment of typhoid fever. The important indication in the disease was to remove the toxic material from the ulcers of the intestines and to lessen the number of the bacilli there congregated. For this, the important thing was to drain the ulcers by vigorous purgation. Most physicians hesitated, because they feared that it would hurt the already diseased intestines. For this there was no good ground in the experience of those who had tried purgation. Dr. Thistle had purged his patients for fifteen years, and considered that his mortality had been lower than that of most of his colleagues. He gave calomel in small doses at the beginning, followed by half an ounce of magnesium sulphate; after this the bowels were kept open freely.

Dangers of Purgation.—Dr. Calwill of Toronto said that purgation was a dangerous treatment in his opinion for typhoid fever. Of his cases, those suffering from constipation had a mortality of only 8 per cent. Those suffering from diarrhea had a mortality of 18 per cent. Whenever diarrhea occurred in typhoid fever he always gave a guarded prognosis, and, if it could not be checked, a grave prognosis. On the contrary, he always encouraged constipation, and felt secure of his patients when there was no looseness of the bowels. In his opinion there must be no purging in typhoid fever.

Typhoid Not an Intestinal Disease.—Dr. McCrea of Baltimore said that the question of purgation in typhoid depended on whether it was considered a general or a local disease. Now pathologists considered that the ulcers in typhoid fever were not the primary manifestation of the disease, but only secondary. Typhoid fever was a constitutional disease that usually, but not always, produced ulcers in the intestines. Antiseptics were of no use, because they could not be given in sufficient strength to produce the expected results. It was to no advantage to destroy the bacilli in the intestine since there were so many in other parts of the system. Even in Asiatic cholera, exclusively an intestinal disease, antiseptics had not filled expectations. The speaker considered that the proper eliminants in typhoid fever were the kidneys, and not the intestines. To encourage kidney elimination, the best method was the bath treatment, which stimulated kidney function. Purgation was harmful in all infections, even in those which had not intestinal lesions, as scarlet fever and pneumonia; diarrhea must not be encouraged. The best proof of the value of the water treatment of typhoid fever was furnished by recent statistics from Brisbane. There 1,800 cases had been treated without baths, with a mortality of 14 per cent. Afterwards, bathing had been introduced into the hospital, and an equal number of patients taken from the same class of people, treated in the same hospital in exactly the same environment, gave a mortality of only 7 per cent. Dr. McCrea had been an advocate of purgation, and became a convert to the good influence of constipation by seeing the results.

Dr. Neilson of Milwaukee, Wis., said that in a case recently under his charge, because of severe hemorrhage, he had locked up the bowels absolutely for ten days, yet the patient had done very well.

Results of Purgation.—Dr. McPhedran of Toronto said that in one hundred and ten cases treated by purgation methods at the Toronto Hospital, there had been eleven hemorrhages and three perforations. This showed the effect of disturbing the bowels. He disapproved entirely of the idea of purgation, and thought that intestinal antiseptics were so only in name.

Bacilli After Typhoid Fever.—Dr. Barker of Baltimore said that the best proof that the removal of the bacilli was not the proper indication in typhoid fever, was the fact that after the cure of typhoid many bacilli remained in the body. These were passed in the urine for months afterwards, and their presence must not be forgotten. How the tissues learned to live with these dangerous hosts of bacilli with impunity was the all-important question to be considered.

Dr. Hamilton said that some patients should be treated by purgation and some by antiseptics, but no general rule could be laid down.

SECTION ON SURGERY.

Third Day—Thursday, August 23.

Case of Banti's Disease.—Dr. John R. Williams of Rochester, N. Y., presented a man, twenty-seven years old, who sought advice because of sour stomach and distress in the upper abdomen. His family and previous history were negative. His trouble began in 1900, when he was sick for six months, acutely so during the last two weeks of that time. In 1905 he suffered severe attacks of similar nature. The stools were black and tarry, and the vomitus contained a small amount of blood. Now he suffered no pain except when he had diarrhea; he complained more of a feeling of distress in the epigastrium. He never had any bad habits. There was some pigmentation of the skin. The mucous membranes were pale, and the sclerotic was glistening. The most interesting feature of the case was the enlarged spleen, which practically filled the upper left quadrant of the abdomen. The liver was not enlarged. He had a functional systolic murmur. The leucocytes fell between 4,000 and 6,000. The red cells numbered 3,400,000, and the hemoglobin was 80 per cent. The differential count showed the small lymphocytes to be 11 per cent. and the

large 14 per cent., while the polynuclears were 75 per cent. Normoblasts and an occasional megaloblast were seen in the blood.

Case of Hip Joint Arthroplasty.—Dr. Dow of Regina, Sask., showed this patient.

The Surgical Treatment of Ulcerative Colitis.—Dr. Ingersoll Olmsted of Hamilton read this paper, referring to the various operative treatments that had been employed. Good results seemed to follow any operation which permitted free irrigation of the bowel. Appendicostomy had many supporters. He reported four cases in which colostomy was the operation.

Dr. Robert F. Weir of New York told of how he had devised the appendicostomy operation by accident. In the Philippines American surgeons had opened the colon, made an artificial anus, and irrigated the bowels in cases of colitis. But this left a very disagreeable complication to deal with. Dr. Weir's experience had been with seven cases, five being the ordinary ulcerative, and two the amebic form of dysentery. More difficulty was found in curing the amebic forms. So far there had been as many as eighty or ninety cases treated by this method, and the majority of them yielded promptly to treatment. Experience had shown that the mere flushing out of the colon with large quantities of physiological saline solution was followed by good results. He called attention to Dr. Tuttle's discovery that the ameba could not stand cold, and to his employment of injections of ice water into the bowel with good results.

Dr. Arnold of London and Dr. Price of Philadelphia discussed the paper.

Appendicitis; Some Points in Diagnosis and Treatment.—Dr. Herbert A. Bruce of Toronto in this paper said that the most important point in the treatment was that the appendix must be removed; in all cases of acute appendicitis the operation should be undertaken at the earliest possible moment. Therefore an early diagnosis was very important. A differential diagnosis should be made between appendicitis and acute purulent salpingitis, acute colitis, tuberculous peritonitis, acute indigestion, malignant disease of the cecum and of the stomach with peritonitis. Appendicitis usually began suddenly. He emphasized the point that temperature and pulse were not to be relied upon. In more than half the acute cases rigidity of the right rectus muscle was present, as well as vomiting. The sooner after the commencement of an attack that one operated, the better would be the results. No morphine should be administered until the diagnosis was made; when the diagnosis was made, a surgeon should be called at once. If pus was present and it was necessary to transport the patient in an ambulance, Fowler's position should be insisted upon. This position was also of value after the operation. He had had three fatal cases of ileus following the operation, a very dangerous sequela. One should differentiate between mechanical and septic ileus. Dr. Bruce reported cases in which he had operated, the youngest patient being six months, the oldest ninety-eight years.

Mr. H. W. Carson of London reported a series of 100 consecutive appendix cases. There were 62 males and 38 females. The clinical varieties he divided as follows: (1) Quiescent relapsing, 17 males, 13 females; total, 30. (2) Acute catarrhal (operation before abscess formation), 6 males, 2 females; total, 8. (3) Abscess, 23 males, 17 females; total, 40. (4) Abscess with general peritonitis, 16 males, 6 females; total, 22. With regard to the age factor, between four and fifteen years there were 38 cases, of which 35 were acute cases (92.2 per cent.). Above the age of fifteen there were 62 cases, of which 35 were acute cases (56.4 per cent.). In regard to the question of recurrence, it was shown that of the 70 patients operated upon during the attack, 55 (78.5 per cent.) were in their first attack, 12 (17 per cent.) were in their second, and 3 (4.5 per cent.) had had more than two attacks. With regard to the mortality, there was 1 death in 30 of the quiescent relapsing, or 3.3 per cent.; no deaths in 8 acute catarrhal; 2 deaths in 40 cases of abscess, or 5 per cent., and 14 deaths in 22 cases of general peritonitis, or 63.6 per cent. In considering the mortality in reference to the incidence of attack there were, during the first attack, 13 deaths in 65 cases, or 20 per cent.; during the second attack, 2 deaths in 18 cases, or 11 per cent.; over two attacks, 2 deaths in 17 cases, or 11.75 per cent. In considering the deaths from general peritonitis, between the ages of four and ten there were 4 deaths in 6 cases; between the ages of ten and fifteen there were 3 deaths in 5 cases; between the ages of fifteen and twenty there were 2 deaths in 2 cases; between the ages of twenty and thirty there were 3 deaths in 4 cases; in those over thirty there were 2 deaths in 5 cases. Of the complications, there was 1 case of intestinal obstruction in the quiescent relapsing cases. In the abscess cases, there were 6 cases of fecal fistula, 4 of intestinal obstruction, 4 of pneumonia, 3 of subdiaphragmatic abscess, and 1 each of pleurisy, empyema, phlebitis, parotitis, and delirium tremens.

Dr. Price of Philadelphia discussed the paper.

Ulcer of the Duodenum from a Surgical Standpoint.—Dr. William J. Mayo of Rochester, Minn., read this paper. He said that duodenal ulcer was a frequent disease and 40 per cent. of all gastric and duodenal ulcers were situated primarily in the duodenum, yet 90 per cent. of these were called gastric; 96 per cent. involved all of the coats of the intestine and could readily be demonstrated on opening the abdomen. The large majority of ulcers called pyloric were in reality duodenal in origin, as the terminal three-fourths inch of the pyloric end of the stomach was rarely the primary seat of an ulcer, and when involved was usually secondary to duodenal or prepyloric ulcer. The arrangement of blood-vessels was the best guide to the pylorus in accurate localization when adhesions and scar tissue obscured the field. There were 73 per cent. of duodenal ulcers in men and 27 per cent. in women. The duodenum embryologically was not a part of the small intestine but of the stomach, and was concerned in preparing the food for intestinal digestion and absorption. The involvement of the peritoneal coat gave localizing epigastric pain and tenderness, and muscular rigidity confined to the upper right rectus muscle. Chronic perforation and regional peritonitis were common. The thin coats easily permitted penetration, but the small and relatively sterile contents of the duodenum enabled adhesions to form with neighboring viscera. The differential diagnosis was difficult in certain cases between gastric and duodenal ulcer, and occasionally between ulcer and gallstone disease. Complications were numerous, especially obstruction, acute perforation, and recurring hemorrhages. Dr. Mayo then considered the surgical treatment, and said that in cases of acute perforation the transverse suture, with or without gastroenterostomy and pelvic drainage through suprapubic stab wound, the patient being maintained in a semisitting posture afterward for several days, was of value. In acute and dangerous bleeding he advised excision of the ulcer, or a mucous suture protected externally; and for chronic bleeding, excision or gastrojejunostomy, the latter being more beneficial in duodenal than in gastric ulcer. In cases of chronic ulcer, gastrojejunostomy, after posterior "no loop" method, was the operation of choice. Excision, with plastic or end-to-end closure, was occasionally indicated. He reported 188 operations on duodenal ulcer, 10 being acute, with four deaths. There were three acute recurring hemorrhages, with one death. There were 175 cases of chronic ulcers, with two deaths. Of 134 patients operated upon between January 9, 1904, and June 5, 1906, 103 had been traced; of them ninety-three were cured, or practically so, eight were unimproved, and two were worse than before the operation.

Mr. George Cooper Franklin of Leicester said that the diagnosis between gastric and duodenal ulcer was by no

means clear, and could not be made, as a rule, until the abdomen had been opened. Of the symptoms the one that had impressed him most was the intense, agonizing pain which was so prominent, especially in men about fifty years old. The rigidity of the abdomen was an important symptom. In cases of perforation in duodenal ulcer, the diagnosis was far more easy than when perforation had not taken place. A gastroenterostomy was the only operation that would give relief in these cases.

Dr. J. Rose Bradford of London wished to bring before the section three points: (1) He asked Dr. Mayo his opinion as to the truth of the recent views advanced in reference to the pathology of gastric and duodenal ulcer, namely, were they not really dependent upon the production of cell toxins and their absorption by the gastric cells. (2) In reference to the diagnosis, it was interesting to hear Dr. Mayo lay so much stress upon the presence of pain and rigidity to the right of the median line; this he considered to be one of the most valuable of the physical signs in attempting to differentiate between duodenal and gastric ulcer. (3) He asked Dr. Mayo what importance he attached to the presence of melena and the absence of hematemesis. He spoke of a type of case which gave much difficulty in diagnosis, that type occurring in young men under thirty years of age, who, without symptoms of gastric disorder, presented symptoms of marked anemia. These were very difficult cases to diagnose, and also difficult to treat. He also asked when was the best time to interfere surgically. It should be remembered that there were a number of cases of duodenal ulcer in which the patient was struck down suddenly, without any symptoms of gastric disorder, as the result of a copious hemorrhage. In the absence of rapidly ensuing anemia it was a question whether surgical intervention should be instituted at once or not.

Dr. John B. Murphy of Chicago said that Dr. Mayo had forced upon the world the recognition of the fact that duodenal ulcer was more common that was formerly believed, and too much credit could not be given him for this. In 1902 Dr. Murphy published a paper in which he stated that duodenal ulcer was a rare condition; now within four years he was compelled by Dr. Mayo to change his opinion. He contrasted the operative and the postmortem diagnosis. He quoted one author who stated that out of 12,806 autopsies the existence of duodenal ulcer was found in but three cases. To-day, in Rochester, Minn., one could see three cases every day in Mayo's clinic.

Dr. Robert F. Weir of New York said he had collected fifty-seven cases together, and it was shown that the operation would be successful if done within twelve hours after symptoms of perforation developed.

Dr. Teskey of Toronto said that some patients were operated upon for stenosis of the pylorus, so-called, when it was found that the trouble was really in the duodenum.

Dr. Ochsner of Chicago said his experience was not so great as that of Dr. Mayo by one-half. He had found in the lower portion of the duodenum, from 3 to 10 cm. below the entrance of the common duct, a very distinct collection or accumulation of circular muscle fibers. Attention was drawn to this by observing a number of phenomena. During the examination of a large number of cases in which there was vomiting after the use of an anesthetic, they found always present in the vomitus a certain amount of bile. For months the fact had been known that in ileus there was always bile in the vomitus. In cases of duodenal ulcer, he had observed many times that there was severe pain, mostly to the right of the median line, when the stomach was empty. Observations were made in many cases in operating for the relief of gastric ulcer and gallstones, that the lower end of the duodenum was considerably constricted, and the upper end of the duodenum and often the pylorus, was dilated. He then called attention to Cannon's well-known discoveries regarding the use of the duodenum in digestion, etc., and said that, putting all these things together, he was led to make a number of dissections. In his dissections he actually found existing at this point these circular muscular fibers, and when there was an accumulation of irritating substances at this point there was a lack of coordinating sphincter action above and between the circular muscle action below.

Dr. Thomas Callen of Baltimore called attention to the frequency of duodenal ulcer in England, having seen three persons operated on in one day at Leeds.

Dr. John C. Monro of Boston said that Dr. Mayo had brought order out of chaos. The landmarks for finding the pylorus as given by Dr. Mayo were new to him. Many patients had been operated upon for cancer, when in reality they were subjects of duodenal ulcer. With regard to the neurasthenic type of cases of stomach disease, he now refused to operate unless there were definite obstructions, or some lesion which interfered with the pylorus or duodenum. In the after-treatment he now did not limit the amount of liquids taken by the mouth, but at once gave the patients as much as they wished to take, and it seemed to him that they did better.

Dr. Mayo said that blood was found in the vomit in duodenal as it was in gastric ulcer. Since the publication of Dr. Weir's paper in 1900, the work in duodenal ulcer had been largely surgical.

Treatment of Congenital Club-Foot.—Dr. B. E. MacKenzie of Toronto read this paper, and offered the following conclusions: (1) The prognosis in ordinary nonparalytic cases of club-foot was good. (2) The time for active treatment was early in the second year. (3) The deformity of the foot *per se* should be fully corrected; afterward the abnormal relation of the foot to the leg. (4) Anything more than subcutaneous section of tendons, ligaments, and fascia was seldom or never required. (5) After-treatment consisted in the employment at night of a retentive apparatus and by day of a properly constructed leather boot. (6) The open incision and removal of bone was unnecessary and harmful. (7) Radical operations interfered materially with the natural growth and development of the foot. (8) Restrictive methods, either by braces or apparatus, were employed as little as possible. (9) Persistent manipulation improved the development and function of the foot. (10) Operative treatment must be thorough. (11) In persons under fifteen years congenital club-foot might be so perfectly cured as to give practically perfection of form and function. (12) In adults perfection of form might also be secured, but function was sometimes impaired owing to the fixity of habits previously acquired. (13) The time required for active surgical treatment need not be more than three months. (14) Age was no bar to successful treatment.

Dr. Stiles of Edinburgh preferred open operation and not subcutaneous work. He operated as soon as the child began to walk. He did not care how radical the operation was, so long as it corrected the deformity.

Dr. McKenzie closed the discussion.

SECTION ON MEDICINE.

Third Day—Thursday, August 23.

The special subject for discussion at this session was "Heart Block," especially in its pathological and clinical aspects.

Heart Degeneration.—Prof. Aschoff of Freiburg, Germany, opened the discussion on heart block by stating that usually it was considered that general degeneration of the heart muscle occurred as a consequence of most of the infectious fevers. It was taught that these febrile conditions caused inflammatory areas in the heart muscle, and that degeneration set in as a consequence. Careful investigation in Prof. Aschoff's laboratory had shown, however, that

these supposed general inflammatory conditions did not actually exist. In 112 hearts carefully examined in every part, only a small number of inflammatory changes were found. Only diphtheria produced constant inflammatory changes in the heart muscle, and only rheumatism produced characteristic specific nodules in the myocardium. These rheumatic nodules in the heart muscles occurred just underneath the heart covering and were very small, not more than of millet-seed size. They presented certain peculiar large cell elements and reminded the examiner forcibly in many respects of tubercles. There was a regular arrangement somewhat concentric, and giant cells or cells resembling giant cells were always present. Besides these rheumatic nodules the most characteristic pathological lesions were infarcts, the so-called anemic infarcts. These seemed always to be due to thrombosis of the coronary arteries. Most of these, however, were so small that no serious influence upon the heart muscle could be thought to be exercised by them. No progressive myocarditis could ever be found. It seemed, then, that some other reason besides that ordinarily accepted must be found for heart failure and for the hypertrophy and dilatation which occurred so often in heart cases. There had been too much assumption and too little investigation in this matter of degeneration of the heart.

There came the thought, then, that perhaps the occurrence of even minute changes in certain parts of the heart might have a very serious effect. Investigation showed that whenever one special bundle of muscle fibers was affected, then heart failure became a pronounced symptom and death from this ultimately ensued. This special bundle of muscle fibers was the muscle bundle of His, so called because first described by this German anatomist. It was a series of fibers which began near the coronary vein, ran through the auricle down, to be distributed on both the ventricular walls and on the septum. This bundle had been found in all animals, and was surrounded by a special connective tissue sheath which separated it from all others. The branch of it running to the right ventricle was very small, that to the left quite large. These bundles were first described by Durkinje in 1845, in the hearts of calves. They might be seen even with the naked eye in human hearts as a stripe of muscle whiter than the surrounding tissues; in the old, whose hearts had become brown, they could be seen most easily. Unfortunately the pale color they possessed caused them often to be thought the result of degeneration and they had been frequently described as such. In the dog this bundle of muscles sometimes had branches running across the cavity. Occasionally by anomaly such crossings of the cavity were seen in man. The muscle bundle was surrounded by a clear zone of nerve fibers. Any change in this special muscle bundle produced serious effects upon the heart. The stimulus for heart pulsations which arose in the auricle was conducted through these fibers to the ventricle. Any interference with this conduction, as could be easily understood, produced serious results. Section or compression of the bundle caused the auricles and ventricles of the heart to beat independent of one another. A beat that began in the auricle did not pass over into the ventricle, and this was the condition that had received the name of heart block.

This condition had been found to exist especially in what was known as the Stokes-Adams syndrome. It also occurred whenever Cheyne-Stokes breathing was present. In a number of cases actual degenerations of the bundle had been seen. In Prof. Aschoff's experience in one case there had been a distinct sclerosis of the arteries of this bundle of muscle fiber, and in another fatty infiltration had produced compression of it. The speaker declared that the presence of a gumma or tumor in this bundle seriously interfered with the heart action. Sudden death not infrequently took place because of pathological changes here. It was evident that the pathology of sudden death would have to be reinvestigated from the standpoint of more recent knowledge with regard to this part of the heart. Any inflammatory changes, however slight, produced a modification of the heart's rhythm. It seemed to be clear now that all irregular action of the heart must be studied with this fact in mind. In a word, a new chapter in heart pathology and in the study of clinical manifestations had been opened by these observations.

Clinical Heart Block.—Dr. J. McKenzie of Burnley, Eng., said that heart block was one of the most important chapters in the recent development of a knowledge of heart disease. While the German school had to be thanked for much knowledge in the matter, it must be borne in mind that the first hint of the significance of the heart muscle had come from the studies made by Romanes on the heart of *Medusa*. Romanes was a Canadian. Gaskill had further developed the subject. Heart block was now known to be due to a failure of the conduction of the stimulus originating in the auricle into the ventricle. This fact made it much easier to understand the significance of all heart irregularity. These occurred, in Dr. MacKenzie's experience, not so much from suppression or degeneration of the bundle of His as from irritation of it. Various forms of heart arhythmia could be distinguished and the indications for treatment were much clearer because of this discovery. Dr. MacKenzie said that studies of the phenomena of heart block enabled the physician to recognize that in certain cases digitalis could do no good, while in other cases it would be of great service. Instead of the blind groping in this matter that characterized therapeutics in the past and that made so many text-books disagree with one another, so that it was eminently unsatisfactory for the physician to look at more than one of them, definite knowledge would now be obtained. He illustrated by charts from certain cases just how heart block occurred and how the auricle might beat several times while the ventricle was beating but once, and how there might be serious delay in the conduction of the impulse from the auricle.

Physiology of Heart Block.—Dr. Erlanger of Baltimore, Md., said that there was a normal delay in the conveyance of the impulse from the auricle to the ventricle, but when this occupied more than one-fifth of a second the passage of impulses was considered interfered with and heart block developed. Dr. Erlanger had studied this by applying a clamp to the bundle of His in dogs and had obtained various disturbances of the heart rhythm and of the harmony of auricle and ventricle. Slight compression with the clamp produced only delay in the conduction of the impulses. Further compression produced great interference so that the auricles beat twice as frequently as the ventricles, or sometimes three or four times as often. In his study Erlanger found that the vagus seemed to act but very little upon the ventricle and often had no effect, though it had been taught that the vagus had a very serious influence upon the ventricle. The accelerator nerve affected the ventricle but did not influence the auricle so much. In the dog, section of the bundle of His led to the development of breathing of the Cheyne-Stokes type. Cerebral symptoms always occurred whenever there was stoppage of breathing, and the medulla seemed mainly affected. There was question, then, whether the brain or the heart was primary in producing the epileptic and comatose symptoms. It seemed, though, that the brain symptoms might be referred to brain anemia, due to the interference with the heart action. A small amount of both organic disturbances must be considered as present. Gumma seemed to be one of the things that produced heart block without serious complicating symptoms. It was the only hopeful form of the affection. In one case seen with Dr. Osler, complete heart block was cured entirely as the result of the administration of potassium iodide.

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

New York.—As a result of conferences between the States of New Jersey, Michigan, and Ohio, formal agreements for reciprocity in medical licensure have been entered into between those States and New York. The basis upon which reciprocity obtains is a license earned on examination in any one of them. The candidate for indorsement of a medical license must present credentials from the officials of the State Board of Medical Examiners which licensed him, showing that at the time of such application he is a reputable practitioner.

Ohio.—At the recent examination there were 217 applicants (204 physicians and 13 osteopaths); of this number 199 physicians and 11 osteopaths were successful. The percentage of failures of the physicians is thus about two per cent.—a rather remarkable showing.

West Virginia.—Of the forty-four physicians examined at the April meeting of the Board, only twelve were successful.

Colorado.—A new schedule of minimum educational requirements was adopted by this Board at its July meeting. This is a decided improvement, and those who are thinking of taking the Colorado examination will do well to write at once for the latest information.

Laxity in Medical Examinations.—Dr. C. M. Jackson of Columbia, Mo., advocates in the *Journal of the American Medical Association* a more practical examination than the State boards are in the habit of giving. At the same time he expresses his opinion about the style of questions and the general laxity in the methods of examination in many States. He says that "any young man with a good memory could in a few months memorize a set of quiz compends, and (if allowed to try) could pass the State board examinations in many States without ever having seen the inside of a medical college. And, furthermore, in some instances, if all reports be true, he need not even have a good memory, provided that he carry the quiz compend in his pocket!"

Medical Items

Electric Sleep. An Experimental Study with an Electric Current of Low Tension. Illustrated with Cardiac and Respiratory Tracings.—Louise G. Robinovitch declares that there are two ways of inducing electric sleep: by abruptly turning on the required potential at once, or by slowly turning on the current, beginning with a minimum potential and increasing it gradually. The slow method is preferable. The writer has conducted various experiments on rabbits, using an electric current of low tension. The preliminary contractions seem to be painless, for the animal does not cry out. There is always some motor and respiratory disturbance at the moment of closing the current; the animal falls on its side, stops breathing, and convulses. Breathing is soon resumed. The hind limbs are the first to stop convulsing, but the fore limbs may sometimes continue to show fine tremors during the entire experiment. This disturbance is often due to technical imperfections. General and special sensibility and consciousness are abolished in this order. The animal remains limp and senseless as long as the current is kept up. Sleep is at once interrupted by the opening of the circuit. The writer has observed no objectionable manifestations in any of the animals experimented upon. Both the writer and one of her colleagues have subjected themselves to experiments of this kind. The writer gives a description of her sensations during the experiments. The awakening is spontaneous without any uncomfortable sensations. Anesthesia is complete when a current of sufficient potential is used. Tracings showing the cardiac beats and respiration during "electric sleep" are given.—*Journal of Mental Pathology.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending September 1, 1906:

HOW MAY THE MEDICAL AND TEACHING PROFESSIONS COOPERATE TO IMPROVE THE MORAL, MENTAL, AND PHYSICAL CONDITION OF THE YOUNG?*

By S. A. KNOPF, M.D.,

NEW YORK.

I DESIRE first to express to the Academy my deep appreciation of the honor which has been conferred upon me by my having been selected to open the symposium on this important topic. In the short space of time allotted to me, it is of course out of the question to treat this theme as exhaustively and as thoroughly as it should be treated. All I may be able to do is to present some ideas concerning the respective duties of the two professions tending toward the desired end, namely, to attain a better type of American citizen, stronger in mind, higher in morals, and stronger in physique. However, at the outset I wish to say these two professions will be powerless to cope with the problem unless the government and our larged-minded, generous philanthropists cooperate with us in our labors.

To begin at the beginning, we should have the courage to state and to teach that the strength of the nation does not depend upon the number of its citizens, but on the kind; not upon quantity, but upon quality. In order that disease, crime, idiocy, mental and moral deficiency shall not be perpetuated through indiscriminate procreation, we must strike at the root of the evil. I am fully aware of the difficulty we are confronted with when trying to have laws enacted to prevent the syphilitic, the acute tuberculous, the chronic insane and chronic alcoholic, or even only the chronic criminal, or idiot from marrying, but a beginning has been made in some States in this direction, and we should continue our efforts and not be discouraged. In the meantime much can be done by us individually.

The family physician can often by gentle persuasion and convincing arguments accomplish as much or even more than the law, in the direction of preventing marriages when evident disastrous results are to be feared. If marriage cannot be prevented we should do all we can to teach the parents how not to procreate a diseased race. In tuberculosis, for instance, the physician has a divine mission to perform in preserving the life of the tuberculous mother, which is always endangered by pregnancy, and preventing the transmission of a tuberculous diathesis to an innocent child. I feel very strongly on this subject, but, as I have said on previous occasions, I know that there are many worthy men and women, inside and outside of the medical profession, who differ with me. However this may be, I am willing to take the responsibility before the law and my God for each time I have taught a consumptive husband and wife not to procreate a tuberculous child.

It is prevention to which we must look. In order that a child may grow up to as nearly perfect manhood or womanhood as possible its prenatal condition must not be less favorable than its postnatal life. How, for example, can the pregnant woman who is obliged to work in a factory or mill almost until the very hour of her confinement be the mother of a healthy child? From John Spargo's recent epoch-making book, "The Bitter Cry of the Children," I beg leave in relation to this subject to quote the following: "Cases in which women endure the agony of parturition amid the roar and whirl of machinery, and the bed of childbirth is the factory floor, are by no means uncommon. From a large mill, less than twenty miles from New York City, four such cases were reported to me in less than three months. Careful personal investigation in each case revealed the fact that the unfortunate woman had begged in vain that she might be allowed to go home. One such case occurred on the morning of June 27 of last year (1905) and was reported to me that same evening by letter. The writer of the letter is well known to me and his testimony unimpeachable. A poor Slav woman, little more than a child in years, begged for permission to go home because she felt ill and unable to stand. Notwithstanding her condition was perfectly evident, her appeal was denied with most brutal oaths. Cowering with fear, she shrank away back to her loom with tears of shame and physical agony. Soon afterward her shrieks were heard above the din of the mill, and there, in the presence of scores of workers of both sexes, many of whom were girls of fourteen years of age, her child was born." Commenting on this, Mr. Spargo continues: "At present the English law forbids the employment of a mother within four weeks after she has given birth to a child, and the trend of public opinion seems to be in favor of the extension of the period of exemption to the standard set by the Swiss law. So far as I am aware there exists no legislation of this kind in the United States, in which respect we stand alone among the great nations and behind the savages of all lands and ages."

As pathetic as the incident of cruelty to child-bearing mothers related by Mr. Spargo is the graphic description of the life of the married woman, in Mr. Upton Sinclair's recent book, "The Jungle." Here we have a highly sensitive woman with a child under her heart obliged to work from morning till night in unsanitary, depressing surroundings until the very hour of her confinement. The perpetual noise of machinery, the sickening odors, and the overstrain—what results must they produce on the mother and the child alike? Is it a wonder that the women working under such conditions in those stock-yards complain of frightful headaches,

*Opening address for a symposium on this subject presented before the American Academy of Medicine, at its annual meeting, held in Boston, June 4, 1906.

are subject to fits and aimless weeping? Mr. Sinclair is right when he makes the husband of such a woman say that "this work was killing her by inches, she was not fitted for it—no woman was fitted for it—no woman ought to be allowed to do such work —they ought not to marry to have children."

Eli Reclus tells us that among savages it is the universal custom to exempt their women from toil during stated periods prior to and follwing childbirth. In a number of European countries, and particularly in Switzerland, the employment of a mother is prohibited for two months before confinement, and the same period after.

Let us by all means strive to have similar laws enacted and have them rigorously enforced. At the same time let us not fail to impress upon our philanthropists the fact that a charity directed toward making it possible for the future mother to suspend work two months previous and two months after her confinement will be productive of healthier mothers and healthier children.

The newly born child should have its natural food from its mother's breast. Only in rare instances should it be necessary to substitute careful artificial feeding. The malnutrition of the infant, due either to the insufficiency of the mother's milk or ignorance regarding artificial feeding, is by no means confined to the poor alone. Prof. Holt, in his admirable book on "Diseases of Infancy and Childhood," very justly says: "One of the most striking things about children suffering from malnutrition is the vulnerability. They 'take' everything. Catarrhal processes in the nose (adenoids), pharynx, bronchi, are readily excited, and, once begun, tend to run a protracted course. There is but little resistance to any acute infectious disease which the child may contract."

My personal and somewhat extensive experience in tuberculosis has shown me that artificially fed children, and, when there are large families usually the late comers, fifth, sixth, or seventh child, contract tuberculosis more frequently than the first-born and the breastfed. This can be accounted for on the one hand by physiological reasons, on the other by economic ones. The father is older and less vigorous, the mother worn out by frequent pregnancies. The larger number of children to support do not permit the parents to give the late comers the same care and ample nutrition which it was the privilege of the first ones to receive. What can we do to have more breastfed and vigorous babies and thus a more vigorous race, a healthier type of American men and women strong enough to risist a tuberculous invasion, or for that matter any other infectious disease to which a weakened organism easily falls prey? No amount of wealth, no family prestige or social connection can give the child that inheritance which it receives when born of vigorous parents, nursed by its own mother, and tenderly cared for until able to care for itself.

Let the mothers who, for the sake of pleasure and convenience, abandon the divine privilege of nursing their own children change this unnatural practice. I feel certain that if they but knew the difference in the physical and intellectual make-up of their sons and daughters when tenderly nursed by themselves, or when handed over to strangers to become bottlefed babies, they surely would do differently. I know it will be said that not every mother can nurse her infant. This is true in some instances; but to the woman, the future mother of mothers, I like to say that it has been statistically demonstrated that if one generation of mothers fail to give their infants, and particularly female infants, food from the source which Nature has designed, the next generation of mothers will have great difficulty in the natural feeding of their infants. The reverse has also been demonstrated, and it has even been shown that when mothers not fully able to supply the infant with food have supplemented the artificial feeding as best they could with their own breast, their daughters have been able to fulfill the divine duty of nursing their infants, if not always entirely, at least in a much greater degree than the preceding generation. Let us draw a lesson from this scientific fact which is corroborated by Nature's own laws. This lesson once learned, the coming generation of American men and women may yet surpass all other nations in physical beauty, intellectual attainments, and moral strength.

The artificial feeding of a baby should not be left to the discretion of the mother or midwife, but should be taught to well-to-do people by the family physician, and to the poor by physicians designated for that purpose by the Board of Health.

We are all familiar with the excellent work that is done by the Health Department's physicians in many of our cities in teaching the poor how to feed their babies, particularly in summer. This work, often supplemented by philanthropic enterprises, pure milk depots, ice stations, and outings given to mothers and children, has reduced the mortality from summer diarrhea and similar infectious diseases to a considerable degree, but much is yet to be done in this direction. There are so many mothers among our laboring population who have had, owing to early struggles, little opportunity to get even a primary notion of how to keep a house clean, or how to cook plain but good substantial meals with modest means. Cooking lessons in our public schools will, I presume, in time do away with ignorance in the coming generation. But there is many a young mother to-day living in our crowded tenements who would be grateful if she could be taught the lesson of good and economic housekeeping and cooking. Here is a field of the greatest usefulness in which the noble- minded, cultured and educated women may help their less fortunate sisters.*

We are now coming to the point where the cooperation of pedagogics and medicine begins. At what age, and for how long a day, and for how many years should a child go to kindergarten? What sanitary precautions should be taken to prevent the contraction and propagation of disease in such institutions? To every public and private kindergarten a physician should be attached whose duty shold be to examine every child before it is admitted as a pupil. Furthermore, the physician should visit the kindergarten daily so as to discover if any child present is afflicted with an infectious, communicable or contagious disease. If there is one its exclusion with a note to the parents should at once be effected. I do believe that common colds, bronchitis, coryza (which mean often nothing less than a grippe), should be included in this list.

A kindergarten can be in operation throughout the year, and in mild weather the sessions should be held in the open air, on roof gardens or playgrounds. A child can never have too much play of the right kind. The sessions should, of course, not be long and always with frequent recesses. Two hours of kindergarten instruction should suffice between the

* Miss Lillian D. Wald, of the Nurses' Settlement, has equipped for this purpose a flat in the midst of the crowded districts, where model housekeeping is taught and prizes given for the best work.

ages of four and seven. With a few exceptions no child is physically and mentally sufficiently equipped to enter the public or private school for regular instruction before the age of seven. In this conviction I do not stand alone—many authorities in pedagogics and medicine share this opinion, among them the Nestor of New York physicians, my venerable friend, Prof. A. Jacobi.

When the child enters the public or private school to begin its studies in the primary grades a new problem is presented. Its solution depends upon the satisfactory cooperation of the private physician representing the interests of the family; the school physician, representing the Board of Health; the teacher and superintendent, representing the Board of Education, and upon the philanthropist who voluntarily gives his aid to supplement the work of the authorities in their effort to avoid preventable diseases, and develop the minds and bodies of the children entrusted into their care.

In an audience of this type it would seem almost needless to point out the necessity of a thorough physical examination on entering school, a daily inspection and a periodical reexamination of all children, in order to eliminate preventable, contagious, and communicable diseases, and to develop a sound mind in a sound body. I am convinced that through careful daily inspection the morbidity and mortality from such children's diseases as measles, whooping-cough, scarlet fever, diphtheria, trachoma, pediculosis, chorea, etc., would be materially diminished, and has been diminished in communities where school inspection has been carried on with thoroughness. The first examination must, of course, always include an examination for defective vision, defective hearing, defective mastication, glandular growth, vegetations in the retropharynx, deformities, weak or diseased lungs, heart disease, or inferior mentality, etc. That the conditions just enumerated must impair the intellectual state and moral development of any child is obvious. I have no more striking evidence for this than a table kindly furnished to me by Dr. J. J. Cronin, Assistant Chief Medical Inspector of the Health Department of New York, which shows the number of defects found at a recent examination of Truant School No. 120: Eighty-eight boys were examined, and out of these seventy-seven were found defective; in sixty-two anterior glands were discovered; in forty-eight defective vision was discovered; thirty-four had bad teeth; nineteen had hypertrophied tonsils; seventeen had defective nasal breathing; thirteen had skin disease; nine were discovered as having bad mentality; eight had post-nasal growth; three suffered with cardiac disease; two had deformity of extremities; one had defective hearing, and one had a defective palate. It goes without saying that in many of the pupils there was association of defects; thus eight had defective vision and glands, seven defective vision, defective teeth and glands, and so on.

If we remember that truancy is the first stigma of criminality and mental depravity, does it not seem that prevention in this instance is indeed economy? But it is not only the truant who will be morally and mentally benefited by the careful medical examination of the school child and the removal of existing physical defects.

How many times has the deaf child been considered dull and put back in his studies until his defect had been discovered, and, by his removal to a front seat, where he could hear the teacher, he has been made bright and happy! How many times has the myopic or astigmatic child been scolded for not being able to see the drawings on the blackboards or read and write properly, when, with the use of proper glasses, all his unhappiness and seeming lack of intellect and interest had been cured as if by magic! How often has the dull, hard-of-hearing mouth breather been made bright and intelligent by the removal of the vegetations of the retropharynx! While the discovery of such defects as just mentioned lie primarily within the province of the examining physicians the cooperation of the teacher is, of course, inestimable. Both should work hand in hand. Spinal curvatures should be prevented by proper postures, proper desks, frequent change of position, and exercise.

The following table will show the frequency of the diseases, not in the truant child as in the above-mentioned statistics, but in the well-behaved one. For the following summarized report of 7,166 examinations from March 27, 1905, to April 28, 1905, I am again indebted to the courtesy of Dr. Cronin: Number of cases of bad nutrition, 632; of enlarged anterior glands, 1,221; enlarged posterior glands, 417; chorea, 85; cardiac disease, 133; pulmonary disease, 127; skin disease, 126; deformity of spine, 88; deformity of chest, 100; deformity of the extremities, 133; defective vision (objective), 1,273; defective vision (subjected), 517; defective hearing, 265; defective nasal breathing, 843; defective teeth, 1,946; deformed palate, 121; hypertrophied tonsil, 602; posterior nasal growths, 704; bad mentality, 650; requiring medical attention, 3,132.

To show the actual work accomplished by our department for the health of New York City's school children let me add to Dr. Cronin's special report a few figures from the general report made public by Health Commissioner Darlington since the reorganization of the system of medical school inspection of the Board of Health on March 29, 1905. The inspectors have examined 55,332 children, and have reported 18,182 cases of defective teeth, 16,394 cases of defective vision, and 6,182 cases of defective nasal breathing. Treatment was necessary in 33,551 cases. The conditions most frequently encountered were enlarged anterior cervical glands, visual defects, and imperfect teeth, of each of which more than 14,000 cases were recorded. During the last year 88,964 visits were made to the schools by medical inspectors, and 18,844 children were excluded for contagious diseases. Of this latter number 8,833 were for eye diseases, 4,692 for pediculosis, 2,018 for skin diseases, 312 for measles, and 74 for diphtheria. During 1903 65,294 children were excluded, and during 1904, 25,369. Much importance is attached to the work of the school nurses, through which many children that would formerly have been excluded are enabled to continue in attendance.

The curriculum of the school for all classes should be arranged so as not to tax the mind and nervous system to the detriment of the physical development. There should be sufficient physical exercise, particularly breathing exercises. I, personally, favor singing and recitation outdoors whenever the weather permits.

The reason why many of our school children do not sleep enough is, perhaps, in as many instances the fault of the parents as it may be the fault of the curriculum instituted by the Board of Education. Up to its fifteenth year a child attending school should have at least nine hours' sleep in the summer and nine and a half in winter. The overtaxing of the mind and nervous system of the girl at the age when she enters womanhood should be carefully

avoided. In every instance when the pupil feels tired, overworked, and inattentive inquiries should be made at the home of the child concerning its mode of life. In many cases it may be discovered that thoughtless parents impose upon the child the performance of so many household duties that its health becomes undermined. The child labor in the homes of many of our school children is as criminal and disastrous as it is in our factories.

I have known of homes in which the elder children, the boys and girls from ten to twelve years old, were made to do much more housework than many a servant would do, and this in addition to the child's school duties. There is a child-labor problem in far too many homes which, I believe, needs looking after. I have known of homes where the mother had died and the care of four younger children, ranging in age from one to eight years, was left to the oldest daughter, a girl of ten, truly a little mother, but a martyr at the same time. The father did not realize the condition until the child mother became ill and contracted tuberculosis. The child-labor problem confronts the physicians and educators who wish to improve the mental, moral, and physical conditions of the young, with all its perplexities.

I hold child labor the curse of our nation, responsible for the frequency of tuberculosis in childhood, and for the prevalence of nervous diseases in children, young men and women, and last, but not least, responsible for alcoholism in the young. How can we expect the delicate growing system of a child, wrecked often by eight or ten hours' day labor, and in some instances even by long hours of night work, to resist the temptation of drink? I cannot enter here into enumeration of the States in which, be it said to their shame, child labor is still permitted to exist.

Felix Adler, speaking in New York the other day, declared that child labor in the United States was steadily increasing. There are, he stated, 10,000 children working about the mines, 7,000 in the glass industry, and 60,000 in the Southern textile mills. There are many noble men and women endeavoring at this moment to combat this fearful practice by the enactment and enforcement of child-labor laws. No less a personage than our distinguished President has taken up this question, hoping to accomplish the suppression of child labor throughout the land. President Roosevelt, in his recent message at the opening of the last session of Congress, recommended in strong terms a model child-labor law, in order that Congress, by wise and discriminating legislation for the District of Columbia, might set a worthy example to the States in which it has no power to legislate on this subject. Permit me to read to you a few passages from an appeal regarding this bill issued recently by the National Child Labor Committee,* which, I think, speak for themselves: "We request the friends of the twenty-nine million children under sixteen years of age in the United States, for whose industrial guardianship, and for the protection of whose rights to healthy physical development, education, and leisure the National Committee is organized, to cooperate in recommending this bill to the favorable attention of their members in Congress. It will mean much for our cause in every State to have the National Capital a reasonably strong and fair law on the subject of child labor. Members and friends of local child-labor committees, of educational, charitable, and philanthropic societies, of women's clubs, and all other organizations interested in this movement, are earnestly requested to write to their respective senators and members of Congress, sending them, if possible, the inclosed copy of the bill to be presented, and urging the passage of this bill."

From Commissioner Darlington's report you must have noticed the large number of children (18,182 out of 55,332) who had defective teeth. I would not wish to recommend free dental service for all school children, but it would seem to me well to urge the parents who are able to have their children's teeth attended to at their own expense. The children of the absolute poor should be attended to by a dentist employed by the Department of Health or Board of Education.

We have found it advantageous in New York to treat trachoma in a room fitted for that purpose in the school building. The children treated thus did not lose one-tenth part of the time that was formerly consumed by having them go to a distant dispensary, where they often had to wait for hours until their turn came. If we do wish to look after the teeth of our school children, some such arrangement will have to be made unless a dental clinic is located near the school.

Of much greater importance than the care of the teeth in school children is, of course, the care of the eyes and ears. In an authoritative article ("The Eyes and Ears of School Children," *Medicine,* April, 1906) Dr. Frank Allport of Chicago, Ill., says that of the 20,000,000 school children in the United States about 16,000,000, or 80 per cent., are suffering from some eye, ear, nose, or throat disease, which can easily be detected, and generally cured, if the public health and educational authorities will only agree that this work shall be done. Further on he says: "It may also interest students of sociology to know that there are in the United States over 300,000 blind people, many of whom would not have become blind if their disabilities had been detected during school life, and that it costs the public in the neighborhood of $15,000,000 to care for these unfortunates. Reducing the question, then, to the mere sordid standard of money, is it a matter of public economy to neglect the eyes of school children?"

The number of pupils which should be assigned to one teacher should never exceed fifty in the primary grades, and, as far as practicable, the mentally defective should be weeded out and placed either separately or in lower grades, where they can keep up with the work done by the others. This should be done, not only in the interests of the pupils, but in the interest of the teacher as well. A class, in which there are placed indiscriminately the mentally defective and the mentally bright, cannot make the progress the curriculum prescribes, and when the work is forced a nervous strain is put upon teachers and pupils alike.

There should be opportunity for appropriate training of the mentally deficient as well as of the especially talented pupils. Special schools for the unusually gifted have been recently suggested in Germany, "to care for the neglected genius whose labor if properly directed might be of inestimable value to civilization." *

In our anxiety to relieve the condition detrimental to the physical, moral, and mental development of the children let us not forget the teachers, who have also a nervous system. Those of us who have the

*This appeal was accompanied by a copy of a most excellent bill proposed to regulate the employment of child labor in the District of Columbia.

* *American Medicine,* June, 1906.

fortune to come in contact with them should know how often their devotion to duty is the cause of a physical breakdown. Here, as in all such matters, prevention is better than the uncertainty of cure.

I have seen a good number of young ladies who, after they had passed the teachers' examination, became nervous wrecks, a condition which some were not able to overcome for the rest of their lives. They would lose contol of their nerves at the slightest provocation, and, as a result, in spite of their splendid intellectual training, they made poor teachers.

A somewhat more judicious management on the part of the examining board to spread the examination over a greater number of days is all that is necessary to remedy this condition.

I now come to a part of our subject which has been of deep concern to me for a number of years. I refer to the underfeeding of the pupils of many of the public schools who come from homes of the poor. In investigating the causes of tuberculous and scrofulous diseases of childhood, particularly among our tenement dwellers, I came to the conclusion that underfeeding and improper feeding was the primary and even more frequent cause than bad housing and unsanitary conditions in general. Many observers in this and other lands have arrived at the same conclusion. Although in America the investigations along this line have not been carried on as thoroughly as in other countries, enough work has been done by such men as Mr. Hunter, Mr. Spargo, and others, to show the seriousness of the situation. Let me quote again from Mr. Spargo's book ("The Bitter Cry of the Children"): "When it was suggested that 60,000 or 70,000 children go to school in our greatest city in an underfed condition, and when Dr. W. H. Maxwell, superintendent of the Board of Education of New York City, declares in a public address that there are hundreds of thousands of children in the public schools of the nation unable to study or learn because of their hunger, something of a sensation was caused from one end of the land to the other."

Investigations in this matter are not easy, for, be it said to the honor of the average American child of the poor, and of the poorest of the poor, relatively few are willing to acknowledge the poverty of their parents. Here is a story told by a principal of a school to Mr. Spargo. I will give it in the principal's own words. It relates to a little boy called Tony X.: "I went into a classroom and asked: 'How many children had no breakfast to-day? Show hands.' Not a single hand went up. Then the teacher said, 'Why, I am sure that boy, Tony, looks as if he were half starved.' And he really did, so I told him to stand up, and I questioned him. 'Did you have any breakfast this morning, Tony?' I asked. He hung his head for a minute, and then said, 'No, mum.' 'Now, Tony, wouldn't you like to have a good breakfast every morning, some hot coffee and nice rolls?' 'Yes, mum.' 'Well, do you know the Salvation Army, where they give breakfast to little boys who need them?' 'Yes, mum.' 'Well, if I give you a ticket, won't you go there tomorrow and get your breakfast?' The little boy's eyes flashed, and he looked straight at me and said, 'No, mum; I don't want it.' Really, I admired his spirit. Poor as he was, he did not want charity."

Dr. Cronin's investigation shows that about 9 per cent. of children suffer from bad nutrition. Mr. Spargo privately examined in sixteen New York schools 12,800 children, and out of that number 987, or 7.01 per cent., were reported as having had no breakfast at all, and 963—that is to say, 15.32 per cent.—had had a totally inadequate breakfast. But the underfeeding of these children is not only due to "no breakfast," or the inadequate breakfast, but also due to the hasty luncheon, consisting in many instances of a cracker, an apple, a slice of bread, or some cake bought for a few pennies, and sometimes candy instead.

Many countries, particularly France, Germany, England, Italy, and Switzerland, and in our own country a number of cities, have realized that such lunches are not enough for growing girls or boys, and have undertaken to provide children with warm, substantial, and nutritious midday meals, either free or at cost price. Where this has been done it was demonstrated that the pupils have been able to do better work, that there was less disease, that the children increased in weight, and were made happier in every respect. I do not believe in pauperizing, and would always encourage the payment of a few pennies for the luncheon, but I would not be too strict in this matter. I would rather give lunch to ten children whose parents could pay than to have one innocent little fellow suffer from starvation. Where boards of education and boards of health cannot agree on this, let philanthropists come forward to the rescue.

There is one feature in our present system of education and care for the physical development of our young which seems to be neglected in all our primary public educational institutions. I refer to the instructions in swimming and the incidental compulsory bath. Never was I more impressed with the necessity of such instruction than when duty called me to my service on North Brother's Island on the day of the fearful Slocum disaster. I am convinced to-day, as I was then, that hundreds of those little ones could have been saved from the untimely death to which greed, inhumanity to man, and laxity of law had condemned them had they known how to swim. Every well-equipped college has its swimming tank; why should a public school be behind in anything which may not only tend to the physical development of its pupils, but may be instrumental, in case of accident, to save their own lives or the lives of others? I am, furthermore, convinced that compulsory swimming lessons would give to many a pupil, coming from the overcrowded tenement districts, and often unsanitary homes, a cleansing bath which he otherwise would not get.

The playground of the roof garden, and, if possible, a gymnasium, are, of course, as essential, or even more so, than the swimming tank. The importance of gymnastics, the utility of judicious athletics for schoolboys and girls and college students of both sexes, no one familiar with college life, the exuberance of youth, the necessity of outdoor exercise after hours of confining study, would wish to deny. Only against hazing and such sports as experience has demonstrated to have in many instances proved disastrous to individual pupils would I protest. Overtraining, even for such innocent sports as running, boating, etc., has often proved likewise disastrous. Whenever I am called to examine for tuberculosis a college graduate who has distinguished himself in athletics, during his college course, I am always apprehensive, for the prognosis proves almost invariably more unfavorable in such a case than in the average individual.

Wherever the locality permits it, school farms will form a valuable adjuvant in the education of our children. I cannot speak too highly of the pioneer work done in this direction by my esteemed

friend, Mrs. Henry Parson, in New York, to whose untiring energy we are indebted for this beautiful philanthropy.

The First Children's School Farm in New York was conducted by Mrs. Parson on an unimproved site, condemned for a future park, at Fifty-third street and Eleventh avenue, and overlooking the Hudson river. It had been a dumping ground for years. The only available spot in the whole eight acres the first year was 114 feet by 84 feet. No plough in the Park Department was strong enough to break the ground, and a city contractor had to be resorted to for a heavy street-breaking plough. Then lime, rags, wire, bottles, tin cans, and stones were unearthed, but the conquering of difficulties is one of life's most exhilarating lessons. Here was a neighborhood where the rougher element considered they owned everything in sight. They called themselves the Sons of Rest. Going to prison for ten days or six months was simply an incident in their lives, which they spoke of as "Going to Larry Murphy's farm," or "A sail up the river." The city seemed to have forgotten this section. Only unlimited faith in the value to mankind of what one is endeavoring to accomplish can have caused Mrs. Parson to adhere to her work through the worst conditions, opposition, and criticism.

During the summer of 1904 the real work of construction in the park began. Fearing she might lose the ground already gained with these people, should the work be discontinued during the period of park construction, Mrs. Parsons, assisted by her son and daughter, braved the discomforts and continued the work on a smaller area than formerly. At this time the permanent location of the "farms" had been graded, and temporary structures for a toolhouse and a farmhouse had been completed. Mrs. Parsons and her helpers were to be found on the ground daily, from 9 A.M. to 6 P.M., patiently awaiting the arrival of the top soil needed, and receiving applications for the 4x11 plot. "Mrs. Parsons, may I have a farm?" was asked by more than five hundred children, more than half of whom were refused, owing to lack of space.

Mrs. Parson's work has attracted attention throughout the United States. The "farms" have been visited by thousands of persons representing educational institutions of this country and abroad. They are located in the De Witt Clinton Park, in the heart of the tenement districts from Fifty-second to Fifty-fourth streets, and from Eleventh to Twelfth avenues. It is several acres in extent, and now one of the most perfect parks in the country. School gardens have the high indorsement of the United States Department of Agriculture. The latter is constantly occupied in cooperative work with the school gardens in Washington and other cities of the United States.

It is in the study of nature, of plant and animal life, that coeducation can be most advantageously carried on for children. There are as many opponents to as advocates for coeducation, and I have some hesitation in expressing an opinion. In small communities coeducation throughout school life seems to be necessary for economic reasons. Personally, I do not see why partial coeducation at least should not be feasible, and even advisable at certain ages. Between the ages of twelve and seventeen it might be best to have separate classes, preferably separate schools and teachers and superintendents of the respective sexes, as it is during that time that the manliness in the boy and the womanly nature in the girl develop, perhaps, to a better advantage under different environments. In college and university life partial or even complete coeducation would, I think, be less objectionable. During the first two years of my college career I was in a small institution where coeducation was a feature. It always seemed to me that the presence of the ladies had rather an ennobling and restraining influence on the young men.

The teaching of popular hygiene and physiology should be made a part of the curriculum as soon as the age and understanding of the pupil will permit. Teaching the pupils how to prevent such diseases as tuberculosis by cleanliness is certainly a matter of importance. With the growth of intelligence and understanding, with the entrance of the girls and boys into the age of adolescence, the physiology of sexual life and embryology should be taught to them preferably, perhaps, by teachers of their own sex. I cannot too strongly recommend teaching older pupils all that is to be known of how to live a pure and moral life, sexually as in every other respect. They should know the existence of such contagious diseases as gonorrhea and syphilis, and their mode of prevention. Full knowledge in such matters is better than ignorance. Those afflicted with contagious diseases should be excluded until a cure is established.

For tuberculous and crippled children there should be school sanatoria on the seaside or island. There the teacher who contracted tuberculosis in the performance of her duty should be given an opportunity to get well. If the disease is too far advanced to make the continuation of teaching inadvisable, a pension should be provided for the tuberculous school teacher, so as to make her as comfortable and free from care as possible. Atypical children and the mentally defective should be treated in special schools by competent and specially trained instructors.

Private and public schools, college buildings and dormitories, gymnasiums, swimming tanks, etc., all should be models of sanitation, models of ideal lighting and perfect ventilation.

For a nation to look after its children's welfare from their prenatal state to their entrance upon man or womanhood requires the cooperation of intelligent parents, devoted teachers, competent family and school physicians, perfect harmony between health and school authorities, a wise and benevolent government, great-hearted, generous philanthropists; and, besides all this, large sums from the public funds. To the $100,000,000 invested in the public schools in this country to-day a like sum may have to be added for the destruction of unsanitary schoolhouses and the construction of new and better ones; for the employment of more teachers and more school physicians, and the establishment of special school sanatoria. But the money thus spent will be well spent. I, for one at least, could not see the surplus of our wealth better invested than in preparing a higher, stronger, and better type of citizens to take our place.

I know that in presenting to you in this fragmentary way what I think the children of this nation need in order to improve their mental, moral, and physical condition, and enable them to become ideal American citizens, I may be accused of having too vivid an imagination and of hunting unattainable ideals; but upon the type of men and women we make our children depends the destiny of our republic. The whole world looks upon us as the ideal country, and I am convinced that, if we can but make of our children the right type of citizens, we can

sustain this reputation and become the leader of nations. In defense of my (let me trust) pardonable optimism, I will close with words of one of America's greatest citizens, the late Carl Schurz, whose mortal remains we have just laid to rest:

"You may tell me that my views are visionary, that the destiny of this country is less exalted, that the American people are less great than I think they are or ought to be. I answer, ideals are like stars; you will not succeed in touching them with your hands; but, like the seafaring man on the desert of waters, you choose them as your guides, and, following them, you reach your destiny."

16 West Ninety-fifth Street

CLINICAL OBSERVATIONS CONCERNING THE NASAL PASSAGES AND THE RELATION THEY BEAR TO THE ORGANS OF SIGHT AND HEARING.*

By ALICE G. BRYANT, A.B., M.D.,

BOSTON.

OTOLOGIST AND LARYNGOLOGIST TO THE NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN; OTOLOGIST AND LARYNGOLOGIST TO THE POPE DISPENSARY.

In a recent address before the British Medical Association, it was stated that "the health of the people, both bodily and mental, is the principal asset of the nation; without a vigorous and energetic population no nation can make progress, and coincident with the cessation of progress is the commencement of decadence." This ideal condition of the well-being of our fellows is never fully attained, yet is not the province and privilege of our calling such as to ever strive to respond in the highest sense to one's best endeavors in aiding the sufferings of mankind? And in the time we spend together this evening, if we are but led along the way of any new train of thought, our aim and object is accomplished.

This is the age of specialization, when there are subdivisions in specializing. Indeed, do we not grow weary of the term, when the self-styled specialist may be well described as one who may not develop beyond the germifying stage? The remark of Dr. Billings is obviously true, when he said, "there must be specialties and specialists, and the result will be good and evil, but the evils fall largely upon the specialists who attempt to construct the pyramid of their knowledge with the small end as a foundation." The great field of learning as it existed a few centuries ago must have been within the mental scope of one scholarly mind; but in recent years, with the vast progress in learning, far-reaching in all callings of life, note that the development of the specialist plays an all-important part in the advance of science. While medicine may be said to date from antiquity, its more recent offshoots of otology, rhinology, and laryngology have made rapid progress within our day and generation. To illustrate this point, let me call your attention to a remark made some time ago by a former teacher of mine, who is an aurist of world-wide fame. Some forty years ago he graduated in medicine, and decided to go abroad to pursue a course of studies on the ear. He confided his plans to one of his professors, a man of no mean reputation, who met his proposition in this wise, "why, man, there is nothing to do but syringe an ear." To-day we have multiplied and refined our methods of treatment, and, further, we have added score upon score of operations upon the ear, nose, and throat and their adnexa, until it might be thought that the limits of surgery had been reached.

Let us not, however, be too conservative in placing a limit upon the future possibilities of the surgeon in these special fields of research.

It seems to dwell in the minds of many that there is something mysterious and hidden in the study and treatment of the diseases of the ear, nose, and throat. Thus, do we not find at times a notably conspicuous lack of necessary importance attached to the proper methods and treatment of patients suffering from affections of these organs? It is only within the last decade and a half, and notably within the last decade, that the very great development in rhinology has been made, and a remarkable change is shown in the attitude of the specialist toward diseases depending directly and remotely upon the interference with the normal functions of the nose. As a result, the advances have been made not only in the knowledge of the physiological functions of the nose and its histology and pathological anatomy, but they have been followed by greater improvement in examination and treatment.

More careful study on the part of the rhinologist of the importance of nasal and nasopharyngeal obstructions, as the causal factor in producing cerebral symptoms and many diseases of the eye, ear, larynx, chest, as well as stomachic and intestinal disorders and more general disturbances and nervous and reflex conditions, makes it self-evident that the earlier symptoms should not be overlooked. Thus it is all-important and essential to arrest an advance of the disease before the condition has become serious and unalterable. Moreover, it ought now to be evident that treatment at this stage in the greater proporiton of cases is of decided value. Yet how little care is given to these first principles.

It is manifest that the advanced stages of disease are more easily recognized, but our treatment is often only palliative. Further, the earlier evidences of disease are less easily defined, requiring very careful attention, but the treatment is often of real value, accomplishing much for the patient. Would we observe and interpret the changes as seen with the rhinoscopic mirror and the nasal speculum, by the aid of electric and reflected light, probe, and cocaine, we must acquire great patience, time, continual practice, and supervision. However, if more thought were given to these first essentials, we should hear less of the terms catarrh, deafness, and neuralgia. Nor would they be referred to as if they were diseases, instead of pathological symptoms.

In this connection, let us hold to fundamental principles and at once raise the question: "Have we a case of rhinitis; if so, what form, and what has caused it; and, finally, how shall we best treat such a condition?" We should guard ourselves against falling into the too much routine practice of indiscriminately ordering washes, gargles, sprays, nasal douches, and inhalations, and prolonging their use indefinitely. Thus, such treatment at first may be soothing, but later will rather do harm than good. The function of the nasal tissue may be seriously irritated; moreover, it may be injured by such unscientific methods of treatment. Would we think for a moment of syringing a patient's ear, because deafness was complained of, blindly hoping to remove cerumen, unless we had previously examined the ear by ocular inspection and submitted the patient to subject questioning?

Further, I think sometimes the general impression prevails that deafness is also due to a closure of the Eustachian tube. However, such an offhand diag-

*Read before the Women's Medical Association of New York City, January 17, 1906.

nosis has been frequently given when there was no obstructive lesion. But our diagnosis would not be complete until we had carefully examined the patient.

Let us for a few moments, in a brief way, limit our attention to a general description of the anatomy and functions of the upper air tract. We may say that the nasal cavity proper includes the space limited by the nostrils in front and the posterior nares behind. Anatomists divide this cavity into two parts having a septum vertically placed in the middle line. On the outer sides of the nasal cavities are found three, and even sometimes four, horizontal, scroll-like bones called the turbinated bodies or bones. These scroll-like bones, with irregular and somewhat tortuous surfaces, divide the nasal cavities into corresponding meatuses or passages. In each of these passages, except the lower, some one or more of the accessory nasal sinuses or cells open, and in the lower meatus the lacrymal duct has its exit. Moreover, the nasal cavities and their accessory sinuses and cells are everywhere lined with mucous membrane, that extends from the nares in front to the cribriform plate of the roof above, to the pharynx behind, and to the middle ear, antrum, and mastoid cells by means of the Eustachian tube; also to the conjunctiva by way of the lacrymal duct; and note that beneath the mucous membrane in the turbinated bones is a large supply of blood-vessels. We are further told that the epithelium covering the mucous membrane is for the greater part of the columnar ciliated variety, but we meet the exception near the orifice of the nose and in the olfactory region, where we find non-ciliated epithelium, depending upon the functions these various parts have to fulfill.

The nasal cavities serve a fourfold purpose, mainly vocalization, olfaction, respiration, and drainage. Let our interest center upon the functions of respiration and drainage. By means of the former the nasal tract may be supplied with a requisite amount of air, and moreover the air may be sufficiently warmed, moistened, and filtered. The nasal cavities may serve for the passage of currents of air to and from the lungs. These same passages also play an all-important part in acting as a drain for the nose and for the nasal sinuses and cells and lacrymal ducts that have their exits in the various nasal passages or meatuses.

We will now deal with the normal nasal secretion. We are told that about 350 gm. of this thin fluid, with a specific gravity of 1015, is given off in twenty-four hours. Even though the nasal sinuses have some part in the secreting process, it is at first glance difficult for us to realize how such an amount of fluid as a whole can be poured out from the mucous membranes. It is therefore desirable that we should have some definite knowledge of the source and character of this fluid. Of late years much has been written of the nasal mucous membranes. Particularly noteworthy this last year have been the investigations made by Dr. Goodale concerning "The Secretory Mechanism of the Nose." The great value of such studies lies in the fact that we are able to study and to treat in a more scientific way diseases of the upper respiratory tract, now that we more fully understand its secretory mechanism and its histological and pathological conditions. Such studies are not only interesting, but, above all, of paramount importance. It will certainly help in doing away with empirical methods of treatment, as well as many of the multitudinous varieties of agencies which the laryngologists have called to their aid in the past.

It is stated that the nasal mucous membrane is supplied with a small number of serous glands and a supply of mucous glands. But we are told that neither of these serves except in a minor degree as an apparatus for the secretion of aqueous vapor. In addition to these we have a special mechanism by which the greater part of the fluid present in the passages and on the irregular surfaces in the nasal cavities is transuded, namely, through "the canaliculi of the basement membrane and interspaces in the columnar epithelium." "The other component parts of the nasal fluid consist of a varying amount of mucus, derived from degeneration of the epithelial cells, together with migratory leucocytes and cellular detritus. Finally, under certain conditions of external cold, there is added, by condensation, a varying amount of water exhaled from the lower respiratory passages."

One of the important functions of the respiratory tract is to secrete fluid in an amount to keep it moist, soft, and pliable; a lessened amount or excess in quantity would be considered an abnormal secretion. What is more, the secreting function of the mucous membranes might seem in a way to conform to the existing atmospheric condition, to all changes of the day, however varied or however momentary. We shall refer to this point in a later statement. It is essential that as we breathe, the air should pass to the lower respiratory tract in such a way as not to have a harmful effect on the mucous membranes of these air passages.

In this connection let us make notes of a few physiological data as tersely expressed by Dr. Goodale in the paper previously referred to: "First, with regard to the function of the nose in supplying moisture to the inspired air, we know that a very large amount of aqueous vapor is being constantly exhaled under normal conditions, approximately 500 gr. in twenty-four hours. The greater portion of this comes from the nasal mucous membrane. It is found that inspired air, after leaving the nose, on its way to the lower air passages, is practically saturated, so far as its own temperature is concerned, irrespective of external atmospheric conditions, whether these be cold and dry or warm and moist. Although the nose is capable thus of nearly saturating the inspired air, it must not be forgotten that the air, after passing the nose, attains a higher temperature in its course lower down in the lungs. We find that expired air is under all circumstances practically saturated with moisture. It is thus evident that the passages below the nose contribute this difference in moisture." "The amount of moisture which air is capable of holding depends upon the temperature of the air itself, increasing in direct proportion to increase in temperature."

It is desirable to have some definite idea of a normal nose. The question is sometimes asked, "Do you ever see a healthy nasal tract?" We answer, "Yes," for now and again a patient will be referred to us for some possible nasal reflex disturbance when the nasal passages prove to be normal.

A few moments ago we reviewed the anatomy of the nose. Moreover, the passages should be approximately of equal size. We should, however, recall to mind that normally the nasal passage of the right side is a trifle larger than the passage of the left side. Further, we know that a turbinate and septum, or a turbinate and turbinate, should not be in contact at any time, as, for instance, no intermittent touching or touching even when the turbinates are acutely inflamed. The air should be permitted to pass to all points of the nasal tract, and what is more, to reach it at any time. This is necessary for proper ventilation, evaporation, drainage, vocaliza-

tion, respiration, olfaction, and that "the watery nasal secretion be properly humidified." Many of these points have been ably dwelt upon in a number of papers written by Dr. Pynchon.

It is a significant fact that these ideal conditions may not be present; we may have an obstruction, partial or complete, in the nasal passages; then what follows? "The air required by the organism passes with undue force and speed during the act of inspiration, and there eixsts abnormal variation in the nose and nasopharynx and Eustachian tubes and other parts structurally connected with the respiratory tract; and, if obstructions were sufficiently far forward, even in the lachrymal duct, this amounts to a dry-cupping of the mucosa. The membrane becomes congested, edematous, waterlogged, and ultimately hyperplastic, a condition impairing the circulation and vitality of the tissues."

From the above it may be clearly shown that it prepares the way for inflammation and infection that might extend to parts beyond, as, for instance, bringing about pharyngitis, tonsillitis, laryngitis, bronchitis, asthma, pleurisy, or pneumonia, and also preparing a field suitable for the development of tuberculosis. At this point let us mention some of the various causes of interference with normal nasal breathing: Deflected septum (cartilaginous and bony); hypertrophies of the turbinates; hypertrophies of the vomer; hyperemias of the turbinates; intermittent congestions; abnormal growths; foreign bodies; nasal polypi; distortion of vertebral column; retropharyngeal abscess; enlargement of retropharyngeal glands (acute or chronic); hereditary deficiency, causing abnormal approximation of parts; diminutive nasopharynx; hypertrophy of septal mucous membrane; arrest of development of bony frame of nose; paresis of soft palate and pharynx; synechiæ, nasal and postnasal (either fibrous, osseous, or cartilaginous); intranasal deformities from injuries; adenoids; ridges running along sectional lines; septum abnormally thick; perforation of septum with thickened edges; exostoses; ecchondroses; displacement of columnar cartilage; cysts of floor of nose; anterior soft hypertrophies of nasal septum; posterior white hypertrophies of vomer and turbinates; congenitally narrow nose; alæ nasi failing to lift on inspiration; collapse of alæ nasi against septum on inspiration; abnormal plane of the anterior openings of the nose; abnormal contour of pharyngeal vault; or we may have one or more of these conditions coexisting.

At this juncture, permit me to point out in detail certain clinical facts in everyday rhinological practice of general interest to you, dealing, moreover, with timely topics as the cause and effect of nasal obstructions.

We notice, as a clinical fact, that while essentially abnormalities of the turbinates and septum and mucous membrane are most common in adults, in children the glandular organs, as the adenoid and tonsil, are most subject to pathological changes. It is pretty clearly shown that the nasal tracts should not be over-roomy, for the air is not sufficiently warmed, moistened, and filtered, and the mucous membrane becomes dry.

We have an example of the above in cases of atrophic rhinitis. Hence has been explained the benefit derived in such cases from the injection of paraffin in the anterior part of the nose. By causing a partial obstruction, a rarefaction of air takes place and fluid is poured out over the nasal surfaces. What applies to the whole nasal tract being over-roomy, applies to one nostril being more patulous than the other. The work of respiration is unevenly distributed; that is, one side is overworked and the incoming air is not sufficiently warmed, filtered, and moistened. By far the greater room is found in the interior of the nose, and therefore nasal obstruction at either end would be very troublesome.

It is a matter of interest and importance for us to know that the lower turbinate, especially the anterior portion, is the most erectile of all the turbinates, and the posterior part is abundantly supplied with blood-vessels. From the foregoing statements, we judge that more space is needed in the anterior portion to give room for the air currents. One author states that "the anterior extremities of the inferior turbinates are the regions I like best to accuse in an asthmatic."

An important point to bear in mind in normal nasal breathing is that the "breathway" in inspiration and expiration describes very nearly a semicircular curve, including in its tract the region round and about the middle and superior turbinated bodies and corresponding meatuses as it passes to and from the attic of the nose. The inferior turbinated body is not included directly in the paths of the ingoing and outgoing currents of air except in its posterior parts, although it has much to do in contributing moisture to these same currents of air as they sweep along the "breathway."

Suppose there should be obstruction to the air current along the normal path to the attic of the nose from any of the numerous causes enumerated above, would harmful results ensue? Let us consider for a moment the posterior ethmoidal cells and the sphenoidal sinus. We have noted that these both have exits in the upper portion of the nose. It is a matter of great importance that these cells and the sinus should be ventilated and drained at all times, for, if their exits should become obstructed, a sinusitis might follow, and, as a later result, we might have an autoinfection from retained secretions. Suppose the secretion should find its way to the postnasal region, we should have the so-called "postnasal catarrh," more rightly named "a postnasal discharge."

We may have the normal air currents forced to the lower part of the nose, due to a stenosis or occlusion in the normal "breathway." Such a state of affairs might bring about a congestion of the lower turbinate, followed in due time by increase in size and at a later stage by hypertrophy.

Let us be careful not to use the term "postnasal catarrh" or "postnasal discharge" in too careless a sense. Always trace such discharges to their source. We may have affected the aural, ophthalmic, and cerebral regions, the digestive and intestinal tracts, or even a septic pleurisy or pneumonia may follow and the whole system may be included in the vicious chain. Let us now turn our attention to the middle meatus, where, as we have seen, open the frontal sinus, anterior ethmoidal cells, and antrum. The exit for these "air-cells" may be obstructed by the middle turbinate pressing upon the lower turbinated body, or by various other conditions as outlined above as the cause of nasal obstruction or nasal stenosis. Thus we have another source of a "postnasal discharge."

Similar results, as outlined above, may follow from impacted secretions in the "air-cells" or from secretions traveling to the postnasal region. Perhaps in neither of these cases will the secretions be found in the anterior part of the nose, and thus we would resort to the postnasal mirror, or by subject questioning and by other means find the presence, nature, and source of all such nasal secretions. We have seen patients who gave symptoms of their noses being blocked when they assumed the recum-

bent position. It has been called "nocturnal obstruction." It may bring about a restless condition, sometimes insomnia, and, as a later sequence, asthmatic symptoms may follow. An interesting clinical fact is noticed in adult patients. They may have good nasal breathing for all practical purposes, and yet they feel that they are not receiving their full quota of air. A sense of feeling a little smothered exists, and from nasal examination we find the lower nasal tract free, but the upper nasal region slightly obstructed. As evident a clinical fact is to be found in children. Do we not know that a small adenoid may also be in the path of the air current as it impinges upon one or more of the meatuses posteriorly? Have we not found that eczemas of the face are often due to nasal discharges? This occurs frequently in children. It is needless to add that attention directed to the eczematous condition alone would not be attended with the successful results that would accrue from meeting the abnormal nasal conditions.

Further, as a sequence of attic occlusion, we may have an interference with the sense of smell. It is noticeable in cases of ozena. A deep-seated pathological condition may be the cause, but often the other occlusion may be due to some middle turbinate hypertrophy or to some one or more of the numerous causes recently mentioned as a factor in obstructing the normal "breathway." We have mentioned insomnia as one of the results of imperfect nasal respiration; among others, we would note headache, transient or persistent, neurasthenia, melancholia, loss of memory and ambition, giddiness, aprosexia —these may be found in middle turbinate hypertrophy. It has been claimed that epileptic attacks have been sometimes relieved by attending to an obstructing lesion or stenosis in the nasal passages.

One author states that a large percentage of cases of asthma or hay fever is due to some nasal pathological condition, either a sinusitis or nasal deformity, or obstruction, while another author asserts, "I have seen no case subject to hay fever with a normal nasal tract." The singing voice may be impaired by attic occlusion as well as by obstructions in the upper pharyngeal region, and in the first condition we may have the high register impaired. It happens when patients are referred for ear troubles we examine the nose and nasopharyngeal tract, and find sometimes insufficient nasal breathing, although the patients claim that they never had any difficulty in this direction. We, however, direct our attention to the treatment of the nose and the patients soon acknowledge that they must have had in the past some marked nasal obstruction. Let us refer once more to the middle turbinate. We may find it pressing upon the septum, bringing about a local congestion, or erythema, or acne of the nose and face, and even a swollen upper lip; or, from excessive swelling anteriorly, alone or in conjunction with lower turbinate enlargement, producing eye troubles. The lachrymal duct may be occluded or obstructed, or inflammation may extend up the duct to the eye. We may have reflex symptoms brought about in the same way as above, for example as sneezing, coughing, also headache and various so-called neuralgias, while chorea, epilepsy, giddiness, dizziness, and vertigo may also be due to some pressure within the nose.

A prominent laryngologist claims that three-quarters of pulmonary patients have some nasal stenosis, while another laryngologist states that 75 per cent. of laryngeal growths are due to some form of nasal obstruction. As regards a laryngitis due to digestive causes or climatic surroundings, ocular inspection alone might make it difficult for one to decide at once between a laryngitis in its early stage brought about by above causes or one growing out of a tuberculous condition.

We have dwelt at length upon the middle turbinate; we may now pass to a consideration of the lower turbinate. We have previously noted that the lower turbinate, and especially its anterior portion, is the most erectile of all the turbinates, while the posterior part is richly supplied with blood-vessels. We may have a temporary enlargement from inhaling overheated air or breathing in very cold air. An example of the latter condition is seen in numberless cases on cold wintry mornings in our climate. Likewise irritating vapors will bring about a similar condition of this turbinated tissue. Another kind of aftereffect is produced by cold air or cold substances coming in contact with the surface of the body. Normal physiological causes may be productive of swelling of the turbinates. It has been frequently noted that "sudden swelling and sudden collapse of the bodies have been observed to occur under the influence of mental impressions, fright, etc." We again lay special emphasis upon the importance of attending to imperfect nasal respiration.

Reference may be made here to disorders of the aural tract. The influence of impaired nasal breathing, due to obstructive lesions, is the most prolific cause of aural troubles, for the reason that marked variations of air tension thus exist in the nasal and nasopharyngeal tract. "In the very act of swallowing under such conditions the Eustachian tube and middle ear may be robbed of an undue amount of air, that is, a suction process is going on, and transitory or permanent swelling will sooner or later follow."

Ear statistics tell us that 60 per cent. of all ear diseases are due to a faulty condition in the nose or throat. Again, the importance of caring for the nasal and nasopharyngeal tract, having catarrhal troubles attended to, enlarged tonsils and adenoids removed.

Is there a village, town, or city in this country that does not contain a large percentage of persons affected with impaired hearing or permanent deafness, or some serious aural disease? Suffice it to say that only a small proportion have ever sought advice or submitted themselves to systematic treatment. What is more, they seem absolutely indifferent about their condition, and as to a "running ear," they consider it of no importance, or it may be looked upon as "a constitutional error that ought not to be rashly checked."

May we seek to avoid the recurrent and persistent injuries to hearing, and, above all, live our allotted lives and partake of our full share of the beautiful notes that have been so lavishly showered upon us!

The close and most direct connection between the eye and nose is by means of the lachrymal duct that enters the nasal cavity in the lower meatus. This duct is lined with mucous membrane that extends above, where it joins the conjunctiva, and continues below to the nasal mucous membrane. Further, there exists a reflex condition that is normal between the eye and nose. How often we have noticed lacrymation when the probe comes in contact with the nasal mucosa, or we may have an exaggerated condition amounting to a diffuse hyperemia of the conjunctiva when the actual or chemical cautery is used.

There is a strong clinical evidence of an association in children between adenoids and granular lids. It will also be seen that there is even a closer relation between trachoma and adenoids. Clinically, the best, speediest, and most lasting results in such cases

have been due to attention paid to nasal obstruction and the removal of adenoid growths. Should the ocular disturbance alone receive our attention, there will be, in all probability, one or more recurrences of eye trouble and a tedious process of ocular treatment. The foregoing irresistibly leads to the conclusion that a causal connection of some kind exists between the two, and a lymphoid diathesis is found in such cases. Time will not permit me to go into an analysis of cases that might be enumerated almost indefinitely.

In looking over the literature of the subject in the standard text-books of the day upon the eye and nose, it must be universally admitted that they are inadequate in showing the relations that one organ may bear to another in producing various conditions or reflex disturbances.

Among the ocular disturbances arising from nasal affections, we may enumerate the following: Ephiphora; edema of the lids; dacryocystitis; blepharospasm; strabismus; myopia; asthenopia; lacrymation; photophobia; scintillating scotoma; narrowing of visual fields; exophthalmos; diplopia, lacrymal abscess; persistent pain in eyeball; ophthalmia; corneal ulcer; catarrhal conjunctivitis; phlyctenular conjunctivitis; eczematous keratitis; diseases of the optic nerve (neuritis or atrophy); retrobulbar neuritis.

What relation do the eye and lacrymal duct bear to the nasal passages and their accessory cavities and cells? Anatomically the maxillary antrum forms the floor of the orbit, the frontal sinus partly aids in forming the roof, and the ethmoidal cells are closely associated with the lacrymal duct, and have been known to surround the duct. The sphenoidal cavity—or the sphenoidal cavity plus the posterior ethmoidal cells—is in relation with the optic nerve and the ophthalmic artery. We are entering here upon one of the most interesting and attractive of subjects connected with the eye and nose.

The field of research along these lines will develop new problems and new conditions laden with great possibilities and promising rich findings, and there is probably no field wherein the reward will be greater.

The disturbances of vision and development of blindness produced by diseases of the accessory nasal cavities and cells are of grave import. The ophthalmologist and the rhinologist will be more closely associated in the future in their united endeavors to solve these weighty problems.

The statement is heard frequently that "it is nothing but a cold," or "such a child or adult is subject to colds," but can we afford to ignore or consider of no moment "a common cold in the head?" There is a mischievous mistaken idea that it is of no consequence, but it is a grave fault to assume such an attitude. As a matter of fact, as we well know, it may be of short duration, brought about by the merest climatic exposure, or it may be due to some infectious disease, or syphilis or a gouty diathesis may be responsible for the disturbance. What may be the outcome of these neglected, ignored, repeated or continual colds? Innumerable instances might be cited where functional or organic changes of the eye, and more commonly the ear, have been associated with such nasal disturbances. This statement likewise is as applicable when applied to organs far distant from the original seat of trouble. In the management of such cases, as we care for the local condition, let us not be unmindful of more general treatment dealing with hygienic environment and climatic conditions, as well as the employment of medicinal measures; and, last but not least, let us have a proper regard for the "habits of life." The idea that pervades this paper emphasizes the fact that all these questions are of fundamental importance and merit the closest attention, and let us not forget that "each organ is interdependent and correlated with all the other organs of the body, and, moreover, each part has its special function and must be maintained in definite relations to all of the other parts of the system."

An important inference from what has gone before prepares us to make the assertion that no examination of a child should be considered complete until the eye, ear, nose, and throat have been thoroughly examined.

The golden rule in dealing with cases of nasal obstruction is that each case is to be studied by itself and not accepted as belonging to a great class to be treated according to a prescribed rule. And let us give a little credit to Nature, who often cures many diseases. The day is not far distant when the rhinologist will hold as close a relation to the whole system as any other practiser of general medicine.

The foregoing facts irresistibly lead to the conclusion that a clinical connection exists between the oropharyngeal, nasopharyngeal, and aural tracts, as well as between the nasopharyngeal and ophthalmic tracts.

Thus, in the paper of this evening, I have touched only upon generalities, and may they prove to be sufficiently suggestive to further the studies of the general practiser! With these plain truths, founded on a scientific basis, I have attempted to point out the importance of being ever on the alert in detecting abnormal conditions of the respiratory, aural, and ophthalmic tracts, and submitting the same to judicious treatment.

416 Marlborough Street.

A NEW AXIS-TRACTION APPARATUS.*

By ARTHUR C. JACOBSON, M.D.,

BROOKLYN, N. Y.

This device represents an attempt to place the forceps operation on a more scientific plane in that it enables us to employ measured, steady, and precise axis-traction, accomplishing delivery in appropriate cases with a minimum of force and with no expenditure of physical energy on the part of the accoucheur. The power applied is multiplied by a simple mechanical device twenty-five times and hence the instrument is a labor saver, something which we would often welcome in forceps work. At the same time this implies no damage factor, for one cannot pull more with it than eighty-five pounds, a safe and conservative limit. It is true that keeping up the tractions too long and not properly intermitting them, as well as failure to direct properly the line of traction, might and probably would result in damage, but these statements apply equally to manual traction as well. They are not intrinsic faults of mechanical traction.

I shall endeavor to explain briefly and clearly the mechanism and *modus operandi* of the instrument, besides stating some general conclusions. In regard to the last, I may as well say that the whole matter is in an experimental stage as yet and that the conclusions stated represent merely my personal attitude, which has thus far found justification only in the experience afforded by three cases, no one else having employed the instrument.

* Read, by invitation, before the Obstetric and Gynecologic Section of the Eastern Medical Society of the City of New York, May 25, 1906.

First as to the mechanism. (See Fig. 1.) The apparatus is composed of a clamp, which attaches to the edge of a table; an outer case, enclosing a worm and gear (which multiply the power); two rods, the lower one telescoping, joined to the clamp by universal joints; a crank-handle for operating the power-producing mechanism; a hand-wheel at the outer end of the telescoping rod for controlling the transit of the outer end of the apparatus through the orbit which it must describe, when in operation, around the universal joints as pivotal points; a steel tape, which may be replaced by another if kinked without taking things apart, and which winds up on a drum upon which it is held and around which it is guided by a metal case containing an aperture into which the tape passes and which does not itself revolve; a small axle upon which the gear revolves, and a dynamometer (Fig. 2), one of the needles of which is pushed along an as index by the needle proper, remaining at the maximum point reached during the operation for later reference. This dynamometer can be read down to one pound and the needle is absolutely true to scale, whether

Revolution of the hand-wheel to the left raises, to the right lowers, the tractor, the telescoping of the lower rod permitting of this. During tractions the instrument will not rise unless this wheel is turned to the left, which is done whenever the forceps advances and the traction rods cease to remain parallel with the forceps handles.

The steel tape twists upon itself, which, with the lateral freedom of motion through the universal joints, permits of adaptation of the instrument to a reasonable degree of rotation on the part of the forceps.

It is not necessary nor desirable to effect an advance of the head with the first two or three tractions. Run up a moderate amount of traction slowly for a number of times. Tractions should last about one minute only when at their optimum, and one should take at least twenty minutes to bring the head down to the pelvic floor. The occiput must be anterior, the head well flexed, the bladder and rectum empty, the cervix fully dilated, the membranes ruptured, the forceps operation clearly indicated, the diagnosis of position and posture positive, and the

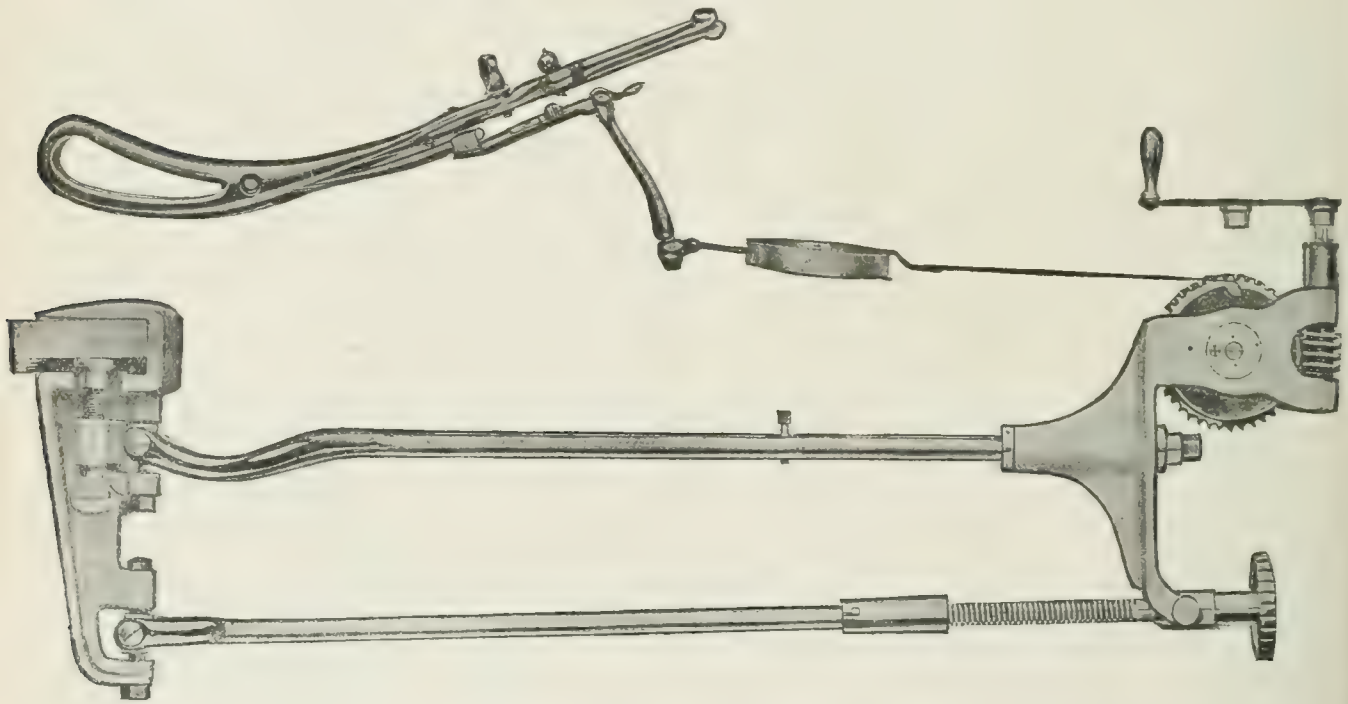

Fig. 1.—Jacobson's axis-tractor

traveling up or down. The apparatus is constructed chiefly of an aluminum composition, weighs about five pounds, and may be taken apart for carrying about.

The Tarnier instrument being applied in a high or median case in which some difficulty in delivery is anticipated, attach the dynamometer to the traction rods of the forceps, connect the tape with the dynamometer, as seen in the illustration, lower or raise the apparatus to the proper point by means of the hand-wheel, *i.e.* until the traction rods are parallel with the forceps handles, align the tractor in its longitudinal axis with the forceps handles; have the patient held in the usual position by two assistants, the buttocks projecting somewhat over the edge of the table with the median line of the body, the vulva and the clamp kept in the same plane, and then, after taking up any "slack" in the tape, begin to apply the traction by means of the crank-handle, the long axis of the instrument being kept always in the same plane as the forceps handles, according as the latter deviate from the median line.

diameters, such as are considered not prohibitive, of axis traction.

In actual practice sterilize the crank handle by boiling, cover the hand-wheel with sterilized gauze, and pin a sterilized towel over the rods and clamp.

The instrument offers certain advantages, some of which are as follows:

1. Accurate measurement of traction.
2. Perfectly steady "pull."
3. Optimum traction at any given stage of delivery capable of being uniformly sustained for a reasonable time; no variation. If it is fifty pounds it remains fifty pounds so long as one wishes.
4. Traction being steady and precise, a minimum degree suffices to accomplish delivery, and thus the damage factor is reduced; hence the method makes for greater safety and conservatism in forceps work, for the degree of compression exerted on the fetal head, we must remember, has been estimated to be about one-half the traction force in pounds, and excessive, jerky, and uneven tractions are certainly causative of maternal and fetal damage; with the

axis tractor not a pound more of power than is actually needed is employed, and all the power utilized is applied with steadiness and precision.

6. Physical exertion on the part of the obstetrician practically obviated; all forceps deliveries rendered easy, and the terrors of the high-forceps operation greatly mitigated.

7. Manipulation of instrument easy; mechanism simple.

8. Slipping of forceps fraught with no danger, as in the case of manual traction, since the power-producing mechanism is at once automatically compromised, so to speak, and traction ceases.

9. Exerts no directive influence of itself, taking its cue entirely from the forceps handles as indicators of the proper line of traction.

10. Owing to control of the rate of advance of the forceps, *i.e.* if the patient is well anesthetized, the danger of bad perineal tears is considerably lessened in cases in which strong manual traction is so apt to eventuate in unexpectedly sudden advance, with consequent rupture of the perineum.

11. In selected cases in which the pelvis is contracted, and in which the forceps operation is elected as the one of choice or necessity, its use should improve the prognosis. Failure should be relatively

Fig. 2.—Dynamometer used with axis-tractor.

rare in the case of the axis tractor in comparison with manual traction under identical conditions.

12. Owing to the gentle, steady, and precise application of the power, the latter, so to speak, being "harnessed," shock should be much lessened in what would ordinarily be severe cases, and, should the forceps fail, one's patient would be in better shape for other procedures. We are, perhaps, all familiar with the disastrous results sometimes consequent upon difficult forceps operations conducted manually.

13. None of the well-known advantages of the axis-traction forceps is abrogated, for the method really represents a logical extension of the principle of axis traction.

I have been asked, What about the patient coming out of the anesthetic suddenly and drawing up on the table, or perhaps rolling over? I can only say that if she be properly anesthetized and properly held this need not happen. As a matter of fact, probably no harm would be done.

You may discern certain disadvantges in the apparatus; some of you may regard it as an obstetric monstrosity. These attitudes may be more or less well founded, though experience will count for more than merely academic opinion as a basis for them. Let us not forget that the Paris Obstetrical Society condemned Tarnier's forceps, and that in America its use was long denounced as gross malpractice. The ordinary, primitive forceps was absolutely condemned in many quarters during the eighteenth century, and I suppose that no instrument has left such a bloody trail of damage in its wake nor a more beneficent and life-saving record behind it either, which seems a paradox, but merely expresses the difference between the human fallibility, ignorance, and prejudice that sometimes sought to guide it, and, on the other hand, the acquired skill, enlightenment, and wise comprehension of its principles that were also displayed. So we must be cautious even in passing upon practical results.

An eminent obstetrician has said: "If experts are to use the axis tractor they ought to prefer accuracy, even though some complexity be necessary to secure it."

In the *American Journal of Obstetrics* for March, 1905, and March, 1906, will be found comprehensive articles by the speaker, fully covering this subject and reporting the results of its use in two cases, one, delivered in a tenement house on East Forty-seventh street, Manhattan, and presenting extraordinary difficulties, the other, delivered at St. Mary's Maternity in Brooklyn. Certain suggestions with respect to interesting research work which the instrument renders possible will also be found in these papers.

I shall here briefly report one additional private case:

Mrs. D., aged twenty-six, native of Scotland, was delivered by forceps of her first child on August 14, 1903, by a Brooklyn physician. Extensive lacerations of perineum, vagina, and cervix. Child lost. Second delivery by the speaker August 16, 1904. Difficult high forceps, position r. o. a. Child saved. Third delivery by axis tractor May 21, 1906, at 4 P. M. No lacerations of mother, and no traumatism to cranial vault of child. Maximum traction, fifty-five pounds. Position right occipito-posterior, which, failing to rotate after sixteen hours' good labor, was converted by internal manual rotation to r. o. a. Head at brim at beginning of forceps delivery. Ether anesthesia. Time of delivery about thirty-five minutes. Assisted by Dr. A. L. Reeve and two intelligent women. Pulse postpartum, 80.

Intercristal diameter, 11 inches; anterior interspinous diameter, 8; posterior interspinous diameter, 3¾; baudelocque, 6½. External oblique: R, 8¼; L, 8¼; total external circumference of pelvis, 31; conjugata diagonalis, 4½; conjugata vera, 3¾; sacropubic, 4½; pubococcygeal, 4; transverse, 4.

Diameters of fetal head: Biparietal, 3⅝; frontomental, 3½; occipitofrontal, 4⅝; suboccipitobregmatic, 3⅜; bitemporal, 3¼; bimastoid, 2¾; circumference, 14; bisacromial, 4¾; bitrochanteric, 3½.

Length of child, 20 inches; weight of child, 10 pounds. Postpartum examination on the tenth day found the uterus anteverted, involution satisfactory, old left-lateral tear of cervix.

It is interesting to note that Tarnier predicted that some sort of perfected mechanical traction would, at a future time, prove of great value in a clinical way. This belief of the master was shared by Guéniot and Pajot. It was declared by them that manual traction was bound to vary according to the muscular force of different individuals and their ability to apply it, and in mechanical traction, could it be properly applied, they saw great advantages. The feeling of these men on this subject cannot be

lightly dismissed on the score that they represent the obstetric thought of a past generation. We have not found them false prophets in other things.

Joulin showed, experimentally, that manual tractions with the forceps, instead of being regular and continuous, or uniformly sustained at their maximum, are abrupt and broken at short intervals, and never uniformly sustained, and certainly this fact has been confirmed by the personal experience and observation of each one of us in his every-day work many times over.

Delivery *per vias naturales,* whenever possible, should be our aim and object, provided that this can be accomplished with reasonable safety to the maternal and fetal structures involved and without material shock. This is nature's intention, and we know that about 70 per cent. of the cases in which the pelvis is contracted undergo spontaneous delivery (Williams). Just as the common law is forceful and authoritative enough for application to the conventional affairs of men, so is the forceps operation usually sufficient unto the demands of conventional obstetric practice. Let us, then, carry this main reliance of ours to its highest development and broadest application.

Just now, when there is such a strong feeling against the high forceps, and when we are running after strange gods as a consequence, it behooves the profession to examine carefully any project which promises a higher evolution in forceps work, which, after all, will always and necessarily constitute the largest phase of operative obstetrics.

NOTE.—Since the above paper was read the writer has delivered a fourth case at St. Mary's Maternity, in which the circumstances were, briefly, as follows:

M. W., apparently about forty years of age (date of birth unknown), primipara, nativity Ireland. Slight contraction in the obstetric conjugate. Examination during labor at full term on June 14 disclosed a face presentation, the position being left mentoposterior. Under ether anesthesia and with good dilatation this was converted into a left occipitoanterior by Dr. P. J. York, the visiting obstetrician. The Tarnier forceps was then applied and the axis tractor attached. Delivery was safely accomplished in about thirty-five minutes with a maximum traction of sixty-seven pounds. Perineum slightly torn. At beginning of delivery the head was slightly above brim. The forceps was reapplied twice during delivery. At this writing, June 15, mother and child are doing well. There was no postpartum shock.

The writer's acknowledgments are due to Drs. York and O'Connell, of the visiting staff, and to Dr. McCullum, of the house staff.

115 JOHNSON STREET.

THE RESULTS FROM THE BLOODLESS REDUCTION OF CONGENITAL HIP DISLOCATION.

BY WALTER G. STERN, M.D.,

CLEVELAND, OHIO.

ORTHOPEDIC SURGEON TO MOUNT SINAI HOSPITAL AND TO THE CHILDREN'S FRESH AIR CAMP.

SINCE the fall of 1902, when "Lorenz came to America," the pendulum of public opinion in America concerning his operation has been swinging to and fro, but is at last coming to rest in the position of "success." The personal experience of the writer extends to fifteen individual hips operated upon by the bloodless method, which are briefly as follows:

1. Girl, age eleven; bilateral reduction successful. Final results, right hip redislocated, left hip anterior transposition to anterior superior spine; high shoe, walks somewhat better than before; result, failure.

2. Girl, four; reduction successful. Final result, perfect anatomical and functional replacement, impossible to tell on superficial examination which hip has been operated upon.

3. Boy, three; bilateral; reduction successful. Final result, right hip perfect anatomical replacement, left hip transposited to upper rim of acetabulum; perfect function.

4. Boy, six and one-half; bilateral; reduction successful. Final result, perfect anatomical and functional replacement of both hips.

5. Boy, nine; left. Failed to reduce.

6. Boy, twelve; left; reduction successful. Final result, anterior transposition, with excellent function.

7. Girl, twelve; left. Failed to reduce.

8. Girl, eleven; right. Failed to reduce.

9. Girl, nine; left. Reduction successful. Final result, anterior transposition, with some external rotation, no aftertreatment, good function.

10. Girl, eight; right. Reduction successful. Final result, anatomical reposition.

11. Girl, seven and one-half; left. Reduction successful. Final result, excellent anatomical and functional result.

12. Girl, four; left. Reduction successful; still under treatment.

In all twelve patients, presenting fifteen hips for reduction, of which I failed to reduce three. These failures were all in old and well-developed cases; all refused a second trial or a trial of Schlesinger's method. There was one total failure, a redislocation due to poor judgment in operating upon an unsuitable case; there were six anatomical cures, one ideal functional result, three transpositions with good function; one patient is still under treatment. The patients were: Male, 4; female, 8. The dislocations were: Unilateral, 9; right, 2; left, 7; bilateral, 3 patients, 6 hips. Final results: hips "suitable for statistics," 11; anatomical cures, 6; ideal functional results, 1; good functional results, 3; failure, 1.

The following is an explanation of the terms used to designate results:

Lorenz first attempted to classify his results in the terms of the anatomical conditions resulting from the course of treatment. Many other writers, including Ridlon, have done the same. It is well known that successful function does not entirely depend upon a successful anatomical outcome, and that many of the so-called transpositions may yield ideal functional results. One writer, Ghillini, denying *in toto* the possibility of ever getting a real anatomical *retitutio ad integrum*, classifies his results entirely as to the functional outcome, and others have followed his example. Any classification of the results of the Lorenz operation must, to be at all accurate, take cognizance of both of these interpretations; it is entirely incorrect to recognize only the anatomical successes as good results and to designate all the others as failures.

The writer's classification of the final results:

Repositiones completæ, ideal results: Anatomical restitutions, perfect functional and cosmetic results.

Very good, good, and fair functional results: Good functional results from anterior transpositions and lateral appositions of all kinds.

Bad results: Bad functional results from anterior transpositions, etc. Bad anterior redislocations.

Redislocations, posterior: Relapses.

Unsuccessful operations: Inability to reduce the

dislocation or to hold it reduced in primary position.

Untoward results: Fracture, paralysis, gangrene, rupture of perineum, etc.

Ideal Results.—By anatomical restitution we mean cases where the limbs are of equal length, the lordosis and waddling gait gone, the joint freely movable, the head of the femur entirely within the acetabulum both to palpation and to the *x*-ray, and where clinically such a hip does not differ at all from a normal joint; or where autopsy findings have revealed femur and acetabulum to stand in normal relation to each other and held in place by apparently normal soft parts. Perfect functional and cosmetic result means practically the same thing, only that clinical examination or the *x*-ray reveals some gross anatomical abnormality, due most likely to the fundamental nature of the primary dislocating forces. The percentage of such cases must, of course, vary with the nature of the cases treated and interpretation of the individual operator. Sherman and Ridlon in America have obtained only 10 per cent. of such results; Burgard in England only 3 per cent.; Lorenz, Lexer, Lange, Nove Jusserand, about 50 per cent.; E. Müller, 70 per cent. of unilateral cases; Hoffa, 75 per cent. of unilateral cases; Narath, 85 per cent. of bilateral cases; Heunser, 80 per cent. of all; Bradford, Lovett *et alli*, 80 per cent. in 1903, while Clark of England claims 100 per cent. in his second series. My own results, seven ideal restitutions in eleven hips, are possibly up to the average, but the advanced age of most of my patients precluded the possibility of a higher percentage of ideal results.

Very good and good results.—A large part of all cured cases fall under this heading. Lorenz, Ridlon, and others speak of anterior transpositions, subspinal positions, and lateral appositions. A description of the exact anatomical conditions referred to by these terms cannot be given in a short paper; suffice it that either from the nature of the parts, the incompleteness of the stretching of the anterior capsule, or the insufficient abduction and external rotation in the first cast, or subsequent instability of the head in the acetabulum, the head of the femur comes to lodge securely against the pelvis, either just anterior to the acetabulum, on its upper rim, or just beneath the anterior superior spine. In these cases the function of the hip joint, both as to stability, ability to walk long distances, and freedom from the disturbing Trendelenburg limp, may be all that can be desired. There remains, however, some external rotation of the limb, stiffness in the gait, and in some cases slight shortening. Undisturbed, a new joint—a nearthrosis—will develop, which insures permanent stability, as shown in one of E. Müller's cases. Lorenz and F. Mueller are not satisfied with these results, but attempt by a subsequent "depression of the head" to force it back into the acetabulum. Results designated as good or fair are of the same character, but on account of contractures or excessive external rotation the function is not as good.

Bad results are seen when the anterior redislocation is excessive, as upon the ramus of the pubes or into the obdurator foramen, etc., or when any of the previously mentioned positions have given bad functional results. These cases should not be allowed to remain as bad cases and an ideal statistic ought not to contain many of them. They should be subjected to repeated secondary operations, and finally —as to be advised for the next group—the bloody operation.

Posterior redislocation and relapses cannot be avoided. Many may be due to faulty technique, but most are due to some natural anatomical obstruction, shallow acetabulum, large head, excessive ligamentum teres, etc. These cases should be repeatedly subjected to the bloodless reduction, and where this finally fails the bloody operation should be done.

Unsuccessful operations are also due to two causes, the most important being the advanced age or excessive muscular development of the patient; this is to be avoided by a more careful selection of our patients; four to six years of age for bilateral cases and seven to ten for unilateral cases should be the upper age limits. Schlesinger's method has, however, advanced the age for successful operations in unilateral cases to about thirteen. Where the malformation of the parts is the chief obstruction to successful reduction, as, for instance, an hour-glass constriction of the capsule, arthrotomy, as advocated by Bradford, allows of perfect exploration and removal of this obstruction. The constant tendency for a reduced joint to redislocate may be overcome by the use of Werndorff's axillary abduction for a number of weeks, followed by the ordinary primary position.

Untoward results, such as paralysis, fractures, gangrene, etc., cannot always be avoided, but are vastly less common than they were before the year 1900, when the use of traction instruments, machines, screws, pulleys, etc., was entirely given up by the best operators. Most untoward results have followed unjustifiable attempts at forcing a reduction in an unsuitable case by the use of excessive force. Since operators have learned that there are many cases which it were better to have left alone and now use only manual force in attempting a reduction, these untoward results are much less common.

Statistics.—In collecting the statistics of the past five years the writer was struck by glaring inaccuracies and discrepancies of all descriptions, and, while it may not be the place of a reviewer to cull the figures, it was absolutely necessary to do so before most of them could be used. In compiling the appended list of 2,600 hips successfully operated upon, I have closely followed the method advocated by Braun, who, in reporting about 180 hips operated on by Prof. Lexer in v. Bergman's clinic, culls out all cases upon whom the operation itself, for various reasons, did not succeed, all cases where there were technical faults, where the aftertreatment was not properly carried out, and all cases where the final results were unknown, leaving him 117 hips "available for statistics." Bilateral cases have been counted as two individual hips, after the practice of Ghillini, Lorenz, and Hoffa. Many instances were presented where the figures did not tally and where the percentages, after given to two decimal places, figured out a fraction of a patient. Figures such as Truel's would often be met, reporting, for instance, fifty cases, "more than half of which were eminently successful." Anterior transpositions are mentioned as in Ridlon's report, without any accurate description of the resulting function. Failures and redislocations were often not enumerated and could only be arrived at by computation. The greatest inaccuracy was, however, the tendency of many writers to figure out their percentages on the basis of all cases seen or operated upon, and not upon the basis of "hips available for statistics." An example of this would be the report of Bradford, Lovett, and others, at the Boston Children's Hospital, for the years 1896-1902. Twenty cases: 1 anatomically successful, 7 unsuccessful, 12 unknown results. In using these figures the writer believes himself justified in so editing the report as to read: 1896-1902: 8 cases

suitable for statistics, 1 successful, 7 unsuccessful. After all, the old saying concerning the four different kinds of lies, "The first is plain lies, the second damned lies, and the other two are statistics," is still quite true.

Conclusions.—The number of hips reported as successfully operated upon since 1900, 2,593. Ideal results, restitutiones completæ, 48.98 per cent.; anatomical restitutions, 41.76 per cent., 1,084; excellent functional results, 7.22 per cent., 187. Good function from transpositions, 39.98 per cent., 1,036. Failure, redislocation, bad function, 12.10 per cent., 314. Discrepancy between failures and good results (about 1 per cent.) is due to inaccuracy of many of the reports.

These figures, gathered from operators scattered all over the world from Athens to San Francisco, are about the same as first given out by Lorenz as his own experience. They come from opponents as well as from adherents to the bloodless method, and consequently fall—as Davis said of his figures—far below the actual experience of individual operators.

Looking at the results from a "functional" standpoint alone and letting them speak either for good or bad results, we have 2,593 cases, with 2,307, or 88.96 per cent., of good resulting function.

Of the individual operators obtaining better functional results are: Ghillini, 308 cases, with 100 per cent. of good results; Narath, 132 cases, 98 per cent. good results; Heusner, 50 cases, 84 per cent. good results; Bradford *et al* in 1903, 28 cases, 100 per cent. good results; Drehman, 95 cases, 97 per cent. good results; B. Lange, 50 cases, 90 per cent. good results; Clark, 25 cases, 92 per cent. good results.

These latter figures are the results that all operators are striving to obtain and which they will and must attain through careful and painstaking work, combined with increasing experience and advanced methods.

AN UNRECOGNIZED ETIOLOGICAL FACTOR IN THE SUMMER DIARRHEAS OF INFANTS.

By JAMES LAWSON WALSH, M.D.,

CASEVILLE, MICH.

From May to October is the dreaded season for bottle-fed babies, depending on cow's milk as their main food supply, on account of the prevalence of diarrheas during these months. Many causes have been ascribed for this condition, but the one most universally held at the present time is that it is of an infectious nature.

Living in the country and observing the milch cows, their feed and their condition during the months on pasture, I am convinced that nine-tenths of the diarrheas of the cow's milk-fed babies are due to a laxative property, contained in the grasses, grains, and weeds on which the cows feed in the pasture during the summer season, and which is secreted in their milk.

The mortality curve keeps pace with the growing grasses, beginning in May and gradually increasing until it reaches its maximum when these grasses are matured in July; then the mortality curve gradually declines with drying and dying of the grasses during August, September, and October. During these later months the pasture is not so plentiful as in the two months previous. The stock are turned in on the stubble of the wheat, oats, barley, cornstalks, etc., also the recently threshed straw stacks, which contain an abundance of new grain which is likewise, in the new state, very cathartic.

The babies most affected with the summer complaint are in the first two years of life and their main food supply is cow's milk. They get the full physiological and often the toxic effect of the aperient properties in the milk from these grass-fed cows.

The lesion is an inflammation of the intestinal mucosa, set up by these poisons, first manifested by indigestion, and increasing either gradually or very rapidly to the severest form of diarrhea and systemic intoxication. The natural functions of digestion and assimilation are at first much impaired, and as the condition continues they are lost altogether until the diarrhea or source of irritation quits or death intervenes.

The consequence of this is that the milk containing these poisons goes through the child, the coagula acting as foreign bodies passing through the whole length of the intestinal tract in this form instead of being digested, irritating as it goes, and is found in the napkin as curds.

The class of patients most susceptible are recently weaned babies, those suffering from marasmus, malnutrition, syphilis, rickets, tuberculosis, dentition, and any predisposing factors to weaken the infant. The high atmospheric temperature will add to the constitutional depression already caused by the laxative properties contained in the milk from

grass-fed milch cows. Neither the barometric pressure nor humidity appears to have any influence.

Another evidence that this is not in nine-tenths of the cases a bacterial disease is that of the etiological factors mentioned in the text none stand good for the whole year, even in the diseases named above. From October to May the diarrheal tendency is either absent altogether or noted only in scattering cases, not in epidemic form such as is found year after year over the whole of the United States and elsewhere from May to October.

Another proof that summer complaint is not due, in nine-tenths of the cases, to bacteria in the milk, is that by sterilization the poison is not destroyed as we would expect it to be if it were due to the streptococcus, staphylococcus and other forms of bacteria, which are readily destroyed by sterilization. It is not a bacterial but a chemical poison, and is not affected by heat, unless perhaps its virulence is thereby increased.

The fact that it happens year after year, beginning with the time the cows are turned out on pasture in April and May (the southern countries being earlier than the northern) and ceasing when the cattle are again stall fed, on dry feed, beginning in October and continuing until May, goes strongly to show that it is due to some poison or aperient contained in the pasture and is eliminated in their milk.

To substantiate what I have said above, let us observe the cows and see how they are fed and what condition they are in when on pasture and when stall fed. In Michigan the grasses are just coming in May, the stock are turned on the new pasture and kept out night and day until September or October. They are ravenous for the new grass (their natural food) and eat greedily of the rich, juicy grasses and clover. The first thing noticed is that they are "scouring," the stools running from them like water, and this condition of their stools lasts until they are taken off the pasture in the fall, yet they get fat. They are again dry fed all winter, when the looseness stops, and they get poor on this feed. The stools are grass green in color and watery, the same color and constituency being found in the summer diarrheas of babies. The color is derived from the coloring matter in the grasses, chlorophyl, and not, as supposed, from the bile.

I inquired from some of my farmer patients whether sucking calves and colts were ever subject to diarrheas while the mothers are on pasture, and was informed that it was a very frequent occurrence and in some it lasted all summer, feces of a grass green color running away from them like water. It frequently happens in those only a few weeks old, and they eat no grass at this early age, depending entirely on the nurse for their maintenance, while with the cows and mares stall fed the calves and colts are more inclined to be constipated and are frequently given castor oil. This latter condition disappears in a few days on pasture.

All this goes to show that there is some cathartic properties in the grasses, which is lost when the grass is dried in the form of hay. These aperient properties of the grasses are conveyed through the milk to the infants, and is in such quantities that there is either an accumulation or an overdose for its years and they are not long in showing the toxic symptoms. Late in the summer a favorite place to pasture the stock is in the orchard, where they can get the wind-falls, which only adds fuel to the fire. I know of a case in which a child had a violent diarrhea, its milk being obtained from a cow that had eaten a great number of apples the day before. In some parts of the country new corn, corn stalks, and green alfalfa will cause ruminants to bloat and will make them pretty loose; milk from these cows will produce a diarrhea in infants almost invariably.

Another convincing point is that new clover imparts the odor and taste to the milk, also leeks, onions, garlic, turnips, and many drugs are readily detected by their odor and taste in the milk of cows eating these products, showing that their active principles are secreted in the milk. It is a well recognized fact that many drugs and some of the above-named vegetables taken by a nursing woman will impart their taste and odor to the milk, affecting the infant on her breast.

I have often observed in my practice that bottle-fed infants' stools in the summertime had a greenish cast to them right along, though the children were not often sick otherwise than a colic and being irritable at times.

A word might be said as to why the prepared foods are not a good substitute for cow's milk during the summer months; it is because they are made from cow's milk largely during the summertime, when the milk is most abundant and because they are prepared for the infant's use with the addition of milk. Also, as they are in part made from the new grains as well as some of the last season's, they carry the same objection as set forth above. My experience with several of these preparations has been most satisfactory during the winter months.

Let me remind you that most all new fruits, vegetables, and grains contain a laxative principle that will set up more or less of a violent diarrhea both in the adult and the young, the severity depending on the susceptibility, the quantity, and the strength of the poison ingested.

The remedy is simple enough: For those children depending exclusively on cow's milk for their maintenance the cow should be kept off of pasture, stall fed as in the winter, being given old hay or well cured new hay. Then, with the proper dilution, according to the infant's ability to digest and assimilate the milk, and attention to cleanliness, the summer mortality of babies will be no higher than that in the winter, and for the same reason.

As to the grasses, their chemistry has not been studied to any great extent, and no aperient properties have been discovered as yet; later research will bring them to light.

Massage in Phlebitis.—Marchais says that the usefulness of massage in the treatment of phlebitis is no longer disputed. He sums up the first part of his discussion by stating that the affected member should be immobilized as long as there is fever, and for fifteen days after the temperature has fallen. When the temperature has been absolutely normal for fifteen days massage and movements may be begun. The veins should not be massaged. For the first four days passive movements of the toes and of the foot are made. Very gentle effleurage is applied to the foot, to the leg, and to the external part of the thigh. During this treatment great care should be taken not to move the affected member from the plane of the bed. No pressure should be made over the saphenous or femoral veins. On the fifth day the patient may himself attempt certain movements, and he may exercise the muscles of his leg. On the tenth day the patient may be able to sit up in bed. Compression is useless and harmful. There will be marked edema, but this will gradually disappear. The writer declares that he has never had any accident in using this treatment.—*Révue Française de Médecine et de Chirurgie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, September 15, 1906.

REFORM IN THE MANAGEMENT OF THE AMERICAN MEDICAL ASSOCIATION.

ALL loyal members of the American Medical Association will read with interest and satisfaction, in the issue of the *Journal* of September 8, the announcement that in future the editor and his fellow officials will obey the mandate of the members, as voiced by the MEDICAL RECORD and other independent journals, that the policy of secrecy in the management of the Association be done away with. Grudgingly indeed, and with abuse of the independent journals, the editor, speaking apparently for the trustees, says that, while "there has been nothing to conceal in the past" and "there is nothing to conceal now," and while "full and complete publicity has always been made regarding everything concerning the Association," nevertheless they will henceforth heed the demand of the members for more light, and will "discuss in the immediate future the various phases of the work of the Association and the reasons for the opposition to it." This we understand to mean that in future the members will be kept informed of what is being done and what the management purposes doing, and how the money of the Association is being spent. The officials could not, of course, admit that they had been forced to yield to the demands of those whom Dr. Happel of Trenton, Tenn., chairman of the Board of Trustees, calls, with subtle humor and a keen appreciation of the dignity of his office, "kickers" and men "with a sore toe," so they have surrendered to Dr. Carstens of Detroit, who published a letter in the *Journal* of September 1, repeating in substance, but mildly and in form of protest, what the MEDICAL RECORD has so often said in criticism of the management.

Apropos of this letter, however, the title, which we assume the editor and not Dr. Carstens affixed to it, is misleading; it reads: "The Attacks on the American Medical Association." We have heard in private, have read in our exchanges, and have ourselves made many criticisms of the management of the American Medical Association, but we have never heard, read in any medical journal, or made an attack on the Association. It is entirely characteristic of the men who have lately been in control, and whose acts have been so severely criticized, that they assert and pretend to believe that such criticism is directed against the Association. It is not, and these men ought to know it is not. The Association is a magnificent body, and should be, and will be when properly managed, the representative of the entire medical profession of the country. No one who is loyal to the profession, and has its interests at heart, can oppose or attack the Association, but he can and does criticize its management, which is so very far from being the Association. This same spirit of *l'état, c'est moi* actuates the reply of one of the trustees to Dr. Carstens' letter, and also this editorial of submission to the will of the members; indeed, it is the substance of the only answer which any one of the officials, when his acts are criticized, ever makes. The best refutation of this false assumption is that the Association—the great body of earnest and honest members—has forced the officers to heed its voice and bring their works into the light. The Association has not been the attacked, but the attacker, and it is slowly but surely reclaiming its rights.

The MEDICAL RECORD has believed, and has repeatedly declared its belief, in the personal honesty of the officials of the Association, but it recognized the fact that the refusal of the management to take the members into its confidence had aroused a feeling of suspicious unrest which not only should be intolerable to the objects of this suspicion, but will seriously impair the usefulness of the Association if not speedily allayed. In these days of the unmasking of corrupt corporation officials every honest man who holds a position of trust should court investigation, rather than seek to suppress it. As Dr. Carstens says: "When such a resolution [to investigate the accounts of the treasurer and secretary-editor] is objected to, it makes men suspicious, and they ask why should anybody object to that? The Good Book says you must not only avoid evil, but the very appearance of evil. This is good doctrine."

We are rejoiced to learn that those in control of the Association have at last been brought to our way of thinking, and if they carry out loyally the promise of reform which they have now made, they will have the cordial support of all the members whose servants they are. There may still be criticism of their acts, but if they accept this criticism in the spirit in which it is made, not resenting it, but meeting it fairly and with good temper, they will learn that it is a tonic, and not an irritant; their task will be lightened, and the Association will enter upon a new era of peace and prosperity. Dr. Carstens says the trustees are lacking in tact. The writer of the editorial of submission, to which we have referred, has not displayed overmuch of this virtue, but he has made a beginning which is full of promise.

THE URINE IN NORMAL PREGNANCY.

PREGNANCY, a physiological process which affects the entire organism of the mother, may logically be supposed to exert a marked influence upon metabolism as expressed by the composition of the urine. This influence is best studied by the careful examination of a large number of specimens of urine from normal pregnant women, and in this light we must welcome a recent article of F. S. Mathews, in the *American Journal of the Medical Sciences* for June, 1906. In this article are recorded the results of an examination of several hundred specimens of urine from normal pregnant women. As a rule, the specimens were taken between the fourth and the eighth months of pregnancy, *i. e.* during the months when the pregnant woman is most apt to consult the phy-

sician for various disorders incident to her state, and when routine urinary analyses are most needed. The author's conclusions, briefly stated, were that "the urine of a pregnant woman, normally and with great constancy, has a specific gravity considerably lower than that of a nonpregnant." This loss of specific gravity Mathews attributes to an increased amount of urine secreted by pregnant women, and to a diminished excretion of urea. The average specific gravity was 1.013—the average amount was 1,500 to 1,800 c.c. (50 to 60 ounces) in the cases in which it was measured, and the average excretion of urea was only 16.20 grams (250 grains) in twenty-four hours.

While the conclusions of Mathews are undoubtedly correct, and tally with those of previous investigators, it is a pity that his research was conducted with the rough technique of the practitioner, instead of the accurate methods of the physiological or pathological chemist. The problem which he attacks requires the most exact methods for a correct solution. Thus his specific gravities were in most instances admittedly taken in specimens which did not represent the twenty-four hours' urine, so that but little store can be set by these determinations. The amount excreted, again, was determined only "at times," and the number of cases in which this was done is not stated; finally the urea determinations were made by Knop's approximate method, which serves well enough clinically, but cannot be regarded as trustworthy in a physiological investigation. Besides, the amount of urea excreted is but an uncertain and variable portion of the total nitrogen eliminated, which alone is a true measure of nitrogenous metabolism. A determination of the total nitrogen in these cases would more justly permit the author's conclusion that some of the nitrogen is retained in the body of the mother to feed the fetus.

Barring the sources of error indicated, however, Dr. Mathews' conclusions are in accordance with accepted views on the subject. Thus, as the normal standard amount of urine excreted by women is lower than in men (according to Yvon and Berlioz 1,100 c.c. in twenty-four hours, instead of 1,500 c.c.), the pregnant women examined by Mathews with their 1,500 to 1,800 c.c. showed markedly increased amount of urine in twenty-four hours. As to the decreased elimination of urea, this point is spoken of in the standard text-books (Ogden, p. 45; Saxe, p. 121, table), where 20 grams is given as the average amount for twenty-four hours in cases of normal pregnancy. This corresponds to the lower limit of normal urea excretion as usually given in the books where the average is stated to be 33 grams (Purdy, Crofton, Ogden), and the range from 20 to 45 grams (von Jaksch, Neubauer and Vogel, etc.), Mathews' figure, 16.20 grams (250 grains), as the average urea excretion of pregnancy, is lower than the figures given by Ogden and by Saxe. Ogden mentions the absorption of nitrogenous material by the fetus as the cause of the diminished urea in pregnancy.

Dr. Mathews has called attention to an important subject. Clinically, it is vital to know that a specific gravity of 1.013, or lower, and a diminished urea percentage in pregnancy do not necessarily mean the presence of renal lesions. The absence of casts, albumin, renal epithelia, etc., will also be in favor of normal kidneys, and if we bear in mind these important characteristics of the urine of pregnant women, fewer errors are apt to occur in our diagnosis and prognosis of renal involvement in pregnancy.

THE EFFECT OF NIGHT WORK ON THE BLOOD.

It is quite universally admitted that light and, conversely, its absence exert a well-marked effect on the animal organism, and that this effect is primarily manifested on the blood. Observers are by no means agreed, however, as to the exact nature and importance of this process, and an examination of the literature on the subject gives one the impression that the effect is a matter of conjecture rather than of actual proof. In view of this uncertainty and of the importance of a definite knowledge of the subject, an extensive experimental investigation was instituted by Gardenghi (*Wiener klinisch-therapeutische Wochenschrift*, Nos. 27 and 28, 1906), in which a considerable number of rabbits and guinea pigs were deprived of light for varying periods and careful observations were made with reference to the changes in the body weight of the animals, in the relative number of the red and white blood cells, and in the hemoglobin and iron contents of the blood. In many cases the morphological changes in the elements were also studied. It was thought advisable to determine the iron in addition to the hemoglobin content, because it has been shown that the relation between these two elements is by no means constant under either normal or pathological conditions.

The results as regards the changes in the body weight are rather interesting; some of the animals gained, other lost in this respect, and the writer accounts for this by assuming that in certain cases the withdrawal of the light resulted in diminished assimilation, in others it produced a slowing of the processes of oxidation. The alterations in the number of red and white cells were so inconstant that no conclusions were possible. A moderate diminution in the amount of the hemoglobin and iron as compared with that in the blood of the control animals was noticeable, however, although the decrease of the iron content was usually less than that of the hemoglobin. The writer is inclined to the belief that this phenomenon is brought about by the decrease in the amount of iron absorbed and in the retarded hemoglobin formation, rather than by a destruction of the previously formed hemoglobin. The reduction varied in both elements from 15 to 22 per cent., a demonstration of the fact that light must have an important bearing on the production of the blood coloring matter in animals as it does on chlorophyl production in plants.

These observations in animals have also been confirmed by the writer in the human subject, and he has found that bakers, among others, show this same constant diminution in the hemoglobin percentage; this can be demonstrated within a short time after night work is taken up, and it soon becomes a chronic complaint. No doubt the same phenomenon could be demonstrated among those engaged in other night occupations, and such workers should

be instructed to remain in the open air during the day, when they are not sleeping, in order to counteract the influence of the absence of this sunlight when at work.

Affections of the Coronary Arteries During Infectious Diseases.

It is a commonly accepted axiom that the behavior of the heart constitutes one of the most important elements in the prognosis of many of the contagious diseases. The failure of this organ has been attributed to several causes, but from certain observations recently made it would appear that changes in the cardiac vessels constitute an important etiological factor. A determination of the existence of such lesions will probably do much to clear up some of the hitherto unsatisfactorily explained cases of "heart failure" occurring during the course of many infectious processes. This subject has been carefully studied by Wiesel (*Wiener klinische Wochenschrift,* June 14, 1906), who found these arteries were almost universally the seat of degenerative changes in the various acute infectious diseases. The preponderance of the muscular tissue in these vessels tends to make this the principal seat of the lesions, although the other coats are also involved; but one of the main points in his investigation deals with the fact that the degenerative changes which occur form a basis for future sclerotic processes and their attending complications. A confirmation of these observations is contributed by Wiesner in the same journal, who also found that the lesions occurring in the vessel walls during the course of the acute exanthemata in children were likely to lead to the development of other processes in later life. In addition to these Wiesner also found similar changes taking place in eclampsia, endocarditis, pyemia, and in cases of acquired syphilis. Here likewise there is to be found an edema of the interstitial connective tissue, as well as an increase of the latter and the elastic tissue. The otherwise closely approximated bundles of muscle cells are thus forced apart and present alterations which can be attributed to pressure atrophy. These observations are of considerable interest, for, as already noted, they aid in accounting for certain cases of sudden death in the course of the diseases referred to, which have often been attributed, for lack of a better reason, to the action of the toxins produced by the particular disease.

Chloroform in Pertussis.

With the advent of the whooping-cough season, certain observations on the treatment of this obstinate and annoying condition recently published by Rothschild and Brunier should prove of interest. A child under treatment for congenital dislocation of the hip and a subject at the same time of an attack of whooping cough, was anesthetized with chloroform preliminary to reduction of the dislocation. It was noted after the operation that the cough had completely disappeared. In another case of pertussis the chloroform was administered with this especial purpose in view, and a similarly favorable result was obtained. In three other instances the sleeplessness and vomiting ceased at once after the anesthesia, but the cough lasted for several days; while in a number of others a cure did not follow the treatment until the end of one or two weeks. The chloroform was given until complete muscular relaxation was obtained, but without the corneal reflex being lost. The narcosis was kept up for from five to ten minutes, and in no cases did any unpleasant sequelæ supervene. The writers believe that the good effects of the chloroform in these cases depend primarily on its antispasmodic action. The cough of pertussis is reflex, and proceeds from an irritation along the interarytenoid region, the nose, or the tonsils. The stimulus finds its way to the centers in the medulla, which have already been brought to a condition of extreme irritability by the toxins of the disease. The chloroform not only exerts a sedative action on these centers, but during its passage along the respiratory passages it also acts as a local antiseptic. A few other observations of a like character are to be found in the literature, but this is probably the most extensive series of cases in which the drug has been used and the favorable results obtained. The simplicity of the treatment renders this therapeutic suggestion worthy of further trial.

News of the Week.

International Tuberculosis Conference.—The International Conference on Tuberculosis was opened at The Hague on September 6 in the presence of Prince Henry of the Netherlands. The French Foreign Minister, M. Bourgeois, was made president. At the session held on September 7 the matter of organizing popular sanatoria was discussed. Among other speakers, Dr. Lawrence F. Flick of Philadelphia urged the foundation of more dispensaries for consumptives, and Dr. Fisher of Berlin insisted that it was absolutely necessary to remove all consumptives from the various military services.

A Tuberculosis Exhibition in Cincinnati.—At a meeting of physicians and others interested in the crusade against tuberculosis in Cincinnati a few days ago, a committee was appointed to arrange to bring to that city the tuberculosis exhibit which has already been shown in New York, Cleveland, Detroit, and other cities.

Abating the Smoke Nuisance.—With the assistance of the Antismoke League, the officials of the Board of Health have for the last two months been waging a vigorous campaign for the suppression of the smoke evil. A great number of arrests have been made in all parts of the city, and offenders have been uniformly held for trial in the Court of Special Sessions early in October. This method of frequent daily arrests has had its effect, and there are now few chimneys giving forth black smoke, except those of the electric power houses of the Rapid Transit Company and the Edison company. The repeated conviction and fining of the engineers of these companies has had no effect, but the arrest of some of the executive officers might avail to stop the nuisance.

Medical Opposition to a Health Board.—The Newburyport, Mass., Medical Club recently invited the State Board of Health to send an inspector to investigate the condition of certain ice-cream establishments, which it was claimed one of the members of the local health board had licensed improperly. The club also presented a petition to the Mayor of the city praying for the removal of the offending member. This man, not a physician, had, it was alleged, spoken contemptuously of the work of sanitarians, and held that cleanliness was not necessary to health. In support of this view he said that the Jewish quarter of the city of New York was the most densely populated and also the most filthy in every respect, and with the very poorest sanitary ar-

rangements of all, yet its death rate was lower than that of any other part of the city. He is also credited with saying that sewer traps are useless and that every honest physician would have to confess that there was no danger in omitting them, and with other heterodox expressions most unbecoming in a health officer.

Doctors and Newspapers.—The Jefferson County (Ky.) Medical Association, the membership of which is composed chiefly of Louisville physicians, at its monthly meeting on August 26, unanimously adopted a resolution in condemnation of the practices of the "newspaper doctors." The resolution made it obligatory on all the two hundred members of the association to refuse to give details to reporters in relation to any medical subject unless the reporters would agree to suppress the name of the informant. The secretary was directed to take note of every newspaper notice in which a physician's name was mentioned, and the newspapers were notified of the passage of the resolution and were requested to assist in enforcing the rule. The morning after the meeting the local papers published an account of it and mentioned the reading of two interesting papers, printing the names of the authors, thus implying that they would not aid in the enforcement of the new rule.

Antivaccination as a Political Issue.—The Pennsylvania Antivaccination League has issued a call for a State conference to be held next week in Philadelphia to consider the advisability of carrying the question of compulsory vaccination into the coming political campaign. The league gave out a letter from a Pittsburgh doctor, who wrote that over fifty physicians in that city had announced their support of the proposed federation of all the antivaccination societies in Pennsylvania, the members of which will be urged to pledge themselves to support only the candidates who will promise to work for the repeal of the compulsory vaccination law.

A Prolific Race.—In spite of extreme poverty, the fertility of the Irish peasantry more than keeps the death rate in check. The annual report of the Registrar-General of Ireland, recently issued, shows an excess of births over deaths of 27,761. The loss by emigration was 30,676, leaving an apparent decrease of population of 2,915. It is estimated, however, that this is offset by immigration, of which no official record is obtainable. The population of Ireland in the middle of 1905 was 4,391,565.

A Quack Imitator of Dr. Lorenz.—The police of a New Jersey town are looking for a swindler who has been operating among the poorer classes, representing himself as a pupil of Dr. Lorenz and offering to cure deformed children for a small fee, payable in advance, of course. After a few manipulations of the affected member he would leave a bottle of liniment and promise to come again, which he never did, however.

Fraudulent Taking of Subscriptions.—The publishers of *Surgery, Gynecology, and Obstetrics* warn members of the profession against the operations of a man who has victimized many doctors by fraudulently taking subscriptions to that journal.

Typhoid Epidemic Due to Infected Milk Supply.—The New Jersey State Board of Health has traced the recent outbreak of typhoid fever in Trenton to the milk supply, and has announced that several dealers are to be prosecuted.

An Experimental Septic Tank.—Recently a conference was held between the secretary and the assistant secretary of the State Board of Health, as a result of which Urbana (Illinois) will probably have in a short time a modern septic tank for the purpose of demonstrating to the officials of the various municipalities the advantages of that method of sewage disposal.

The Enno Sanders Prize.—At the meeting of the Association of Military Surgeons, held in Buffalo this week, it was announced that the Enno Sanders prize had been awarded to Major Pilcher for an essay on "The Training of the Medical Officer of the State Forces to Best Qualify Him for Local Service and for Mobilization with National Troops."

A Shower of Degrees.—On the occasion of the meeting of the British Medical Association in Toronto, the Senate of Toronto University conferred the degree of LL.D. on the following members of the association and foreign guests: Dr. T. Clifford Allbutt, Dr. A. H. Freeland Barbour, Sir Thomas Barlow, Sir James Barr, Sir William H. Broadbent, Dr. H. W. Langley Browne, chairman of the Council of the British Medical Association, Mr. George Cooper Franklin, president of the association, Dr. William D. Halliburton, Sir Victor Horsley, Dr. Donald McAlister, president of the Medical Council of Great Britain, Dr. William J. Mickle, Dr. Louis Lapicque of Paris, Dr. L. Aschoff of Freiburg, Germany, and Dr. William J. Mayo, president of the American Medical Association. Four of the above were also recommended by the Board of Governors of McGill University for the degree of LL.D., these being Dr. T. C. Allbutt, Sir Thomas Barlow, Sir William Broadbent, and Sir Victor Horsley. Several of the recipients of the honor have already been similarly doctored by one or more other universities.

International Homeopathic Congress.—The seventh quinquennial International Homeopathic Congress convened at Atlantic City on September 10, in conjunction with the American Institute of Homeopathy, under the presidency of Dr. W. E. Green of Little Rock, Ark.

St. Louis Medical Society Auditorium.—The dedication exercises of the new medical auditorium of the St. Louis Medical Society of Missouri will be held on September 15, at 8 P. M. The president of the society is Dr. George Homan and the corresponding secretary is Dr. Emund A. Babler.

Hampdon District, Mass., Medical Society.—The members of this society were the guests on August 30 of the Noble Hospital, Westfield, the occasion being the formal dedication of the new surgical building. An address was made by Dr. Edward L. Keyes of this city.

In Honor of Dr. Pozzi.—Professor Pozzi of Paris has been presented with a gold medallion portrait by the sculptor Chaplain and a memorial volume of researches by his former students, on the occasion of the twentieth anniversary of his work at the Broca Hospital.

Dr. Alexander Hugh Ferguson of Chicago has had conferred on him by the King of Portugal a Commandership in the Order of Christ of Portugal, in recognition of his contributions to surgery.

The College of Physicians and Surgeons of San Francisco is to be rebuilt by the board of trustees on the site of the structure burned during the big fire, on Fourteenth street, between Woodward avenue and Jessie street. The building when completed will cost in the neighborhood of $50,000. The trustees hope to be able to construct the first story of their building so as to have sufficient lecture-rooms to begin their course in the autumn.

New East Side School for Cripples.—Plans have been filed at the Building Department for the

five-story school building to be built at 643 and 645 Water street, for the Crippled Children's East Side Free School Society. The structure is to be of brick and ornamental stone, 50 feet front, and 101 feet deep, and will have a roof garden. It is to cost $75,000.

Hospital News.— *Cooper Hospital, Camden.*— It is proposed to add a four-story and basement addition to this hospital, the new wing to contain a children's ward, an operating room, a dining room, and dormitories.

New Hospital in Grand Rapids.—The Board of Public Works of that city has approved the plans for a new city hospital for the care of those suffering from contagious diseases, and called for bids for its construction. The hospital will be three stories in height, and it is hoped to have it completed before winter.

Hospital for the Insane at Fort Smith.—The authorities at Fort Smith, Ark., have purchased a tract of twenty-five acres on the outskirts of the city, and will erect thereon a hospital for the insane.

Season of the Sea Breeze Home Extended.— The New York Association for Improving the Condition of the Poor announces that it has provided so far for about 4,000 outings of ten days each to women and children, and in addition over 18,000 outings of one day. Junior Sea Breeze, the open-air camp for sick babies at Sixty-fifth street and the East River, has been closed for the season, but the home at Sea Breeze, Coney Island, will be kept open until October 1.

A Tuberculosis Sanatorium for Kansas.—The next legislature in Kansas will be asked to appropriate a sufficient sum for the erection in one of the western counties of a State sanatorium for the care of those suffering from tuberculosis. Dr. S. J. Crumbine, secretary of the State Board of Health, has shown by statistics that in Kansas, as elsewhere, there are more deaths from consumption than from any other disease. In July of the present year the reports from the several counties to the State Board of Health show that there were 110 cases of tuberculosis and 63 deaths. In July of last year there were 123 cases and 54 deaths.

Hospital at Taylorville, Ill.—The new St. Vincent's Hospital at Taylorville, Ill., was dedicated with appropriate ceremonies on August 22. The hospital is four stories in height and was erected at a cost of $25,000.

A National Leper Hospital.—It is reported from Washington that Dr. Wyman, Surgeon-General of the Public Health and Marine Hospital Service, will renew his efforts when Congress meets in December to secure authority and an appropriation for the establishment of a leper hospital at some point in the United States. A bill appropriating $250,000 for that purpose passed the Senate in the last Congress, and was favorably reported in the House, but failed of passage because of the opposition of a delegate from New Mexico, who is said to have opposed it under the impression that the Government authorities intended to locate the hospital in New Mexico.

A Railroad Hospital at Temple, Texas.—The Atchison, Topeka & Santa Fe Railroad has adopted plans, and within a few days the contract will be let, for the erection of a new railway employees' hospital at Temple, Texas, which is expected to cost approximately $65,000.

Bequests to Brooklyn Hospitals.—By the will of the late Lewis Luckenbach, the Seney Hospital receives $10,000, and the German Hospital $5,000.

Obituary Notes.—Dr. Henri T. Gaboury of Taunton, Mass., died suddenly on August 28 of disease of the heart, at the age of thirty-five years. He was a French Canadian by birth, and was a graduate of the Medical Department of Laval University, Quebec, in the class of 1892. He had practised in Taunton about twelve years.

Dr. George Mackie of Attleboro, Mass., died August 31 at the age of fifty-six years. He was born in New Bedford, and was graduated from the Long Island College Hospital in 1874.

Dr. E. M. Donaldson of Cedarvale, Kan., died August 28 at the age of sixty years. He was a graduate of the Cincinnati College of Medicine and Surgery in the class of 1877.

Dr. John Theodore Heard of Boston died at his summer home, in Magnolia, Mass., aged seventy. He was a graduate of the class of 1859, Harvard College, and attended the Harvard Medical School. He served with distinction in the medical corps of the Union army during the civil war.

Dr. Edward T. Comegys, a retired surgeon of the U. S. Army, died at Los Angeles on August 31 at the age of fifty-seven years. He was born in Cincinnati, his father being a well-known physician of that city.

Dr. Harriet S. French died at Philadelphia on September 5 at the age of eighty-two years. She was graduated from the Hahnemann Medical College of Philadelphia in the class of 1865, being the second woman in Philadelphia to secure the degree of M.D. She was for many years president of the Pennsylvania branch of the Woman's Christian Temperance Union, and she was keenly interested in the work of the Society for the Prevention of Cruelty to Children.

Dr. C. G. Slagle of Minneapolis died suddenly on August 27. He was born in Ohio, and was graduated from the Medical Department of the University of Louisville in 1861. He practised for a time in Ohio, but about twenty years ago removed to Minneapolis.

Dr. R. C. Carlisle of Newberry, S. C., died on August 21 at the age of seventy years. He was a graduate of the New York University Medical School in the class of 1862. Dr. Carlisle was a practising physician and a successful farmer as well, being one of the largest land owners in the county.

Dr. W. T. Cody of Detroit died of apoplexy in Toronto, where he had gone with a patient, on August 28. He was graduated from the Rush Medical College, Chicago, in 1886.

OUR LONDON LETTER.

(From Our Special Correspondent.)

FALLING BIRTHRATE—INFANT MORTALITY—DELIRIUM TREMENS AND WORKHOUSE ACCOMMODATION — TROPICAL SCHOOL — ABERDEEN UNIVERSITY—OBITUARY.

London, August 24, 1906.

The Registrar-General's quarterly report (April, May, June) repeats the story of a decline in the birthrate. The subject is perhaps welcome to some of the newspapers in this dead season. There are still a few followers of Malthus among us who regard the returns with satisfaction, but the vast majority look upon the record as disquieting. For this second quarter of the year the rate per 1,000 of persons living was 27.5. Two years ago the rate was 27.9. The decline began in 1877, after a slow upward movement, with considerable fluctuations. The decline has gone on regularly and steadily. The difference between birth and death rate when the change set in left a net increase of population of 15.4. Two years ago it was only 11.7. It is sug-

gested that an earnest determination to prevent the excessive infant mortality would compensate for the decline which seems so strangely persistent. On the other hand, while preventing the preventable, there is no necessity for diverting attention from the phenomenon which is puzzling statisticians.

The subject of excessive infant mortality above referred to is constantly recurring, and its causes and prevention have been discussed time out of mind. At the recent historical conference on the subject the same statements were made that have been made by previous observers, but the national conscience is still undisturbed. Fresh statistics reinforce the conclusion that maternal factory employment coincides with high infantile mortality. The percentage of married and widowed factory workers to the whole population in five different towns was twelve, and the infantile mortality 193. In thirteen other towns, with percentage of 6 to 12, the mortality was 156. In eight towns with female factory workers, percentage of 6 or under, the infant mortality was 149. In some other parts statistics are even less favorable, but the foregoing are sufficient to justify the movement towards restricting work by these women. The question has been before Parliament, and although the evil is generally recognized, an attempt to meet it is postponed for the consideration of party politics. It is suggested that pregnant women should not be allowed to engage in factory work, and that the disqualification should be extended for three or more months after delivery. To medical men the propriety of such a measure needs no advocacy. The plan of carrying it out is another question. Among an ignorant and careless population, accustomed to no interference with so-called freedom, it would be difficult to formulate a method which would be acceptable. The idea of restricting pregnant women from one class of work would be resented and other forms of labor no doubt substituted. It would be easier to restrict the suckling mother, or rather the mother who ought to be suckling, because the fact of delivery is registered and factories could be forbidden to employ a woman for a definite period after the birth of a child. This would be good for mother and child too, and would probably bring abut a decrease in the death rate of infants. Numerous proposals have been made while awaiting legislation. Piles of papers have been printed advocating this, that, and the other method of meeting the evil, but none seem to go to the root of the matter. They hint that education will extend, and the dense ignorance of the poorer mothers will be dispelled, and that then they will return to a more natural mode of life. Our publicists do not tell these mothers that it is their first duty to suckle their children, and if they did, the example of the upper and middle classes would be the answer. For these classes are guilty of the same injustice to the children they bear. Bringing up on the bottle gives the mother so much more liberty that too many follow the pernicious practice, to the great detriment of their offspring. With these classes it is possible for medical opinion to have some influence. But there is a great countervailing influence in the press, which is crowded with advertisements and recommendations of all sorts of substitutes for breast milk. The question of a pure milk supply thus often takes the place of prominence in these discussions, and is in itself of great importance for infants, for invalids, and for the general consumer But for infants it is necessary to insist that the purest supply and the most perfect artificial foods are only substitutes for breast milk, useful indeed when that fails from any cause, or even needs supplementing. But every healthy mother should regard it as her first duty to give her offspring the nourishment provided by nature.

With regard to the laboring classes there is something worse to consider. When 20 per cent. of a man's wages goes to the public house, the wife has little chance of keeping a comfortable home for a family. Knowing no other way of increasing her resources she goes to the factory to get a little ready money for the new demand. Education, hygienic homes, etc., have numerous advocates. The labor members of Parliament are in favor of all, provided they are free, for the boasted independent elector seems to have discarded his independence and asks for everything that may benefit him, on the sole condition that it shall cost him nothing.

One of the problems of the Poor Law guardians relates to the maintenance of cases of delirium tremens It is said that the number of such troublesome cases is much greater than people are aware of. In some instances injuries have been inflicted on the attendants, and there seems no redress. The patients are legally temporarily insane, and so irresponsible. The guardians cannot recover the cost of their maintenance. A medical officer lately declared that if children were taken to the wards and shown these drink lunatics they would never get drunk themselves. That may be doubtful, but those who can ought to be made to refund the cost they have incurred. One board has decided to have these patients brought before them before discharge and censured, in the hope that shame may prevent some of them repeating their misconduct. As a further help to such the board will print their names and addresses on the agenda of the next meeting. This will confer on the offenders a little unenviable publicity in their own neighborhood.

King Leopold yesterday received Sir A. Jones and representatives of the Liverpool School of Tropical Medicine, and expressed satisfaction at the results of their investigations into sleeping sickness. His Majesty decorated Professors Boyce, Ross, and Todd.

In connection with the quartercentenary of Aberdeen University, the Lord Rector, Sir F. Treves, has received the honorary membership of the University of St. Petersburg.

Dr. John Cameron, consulting physician to the Royal Southern Hospital, and formerly lecturer on medicine at the Liverpool Royal Infirmary, has died at the age of 88. His first diploma was dated 1839, his M.D., Glasgow, 1843. In 1859 he took M.R.C.P., London and was elected a fellow in 1873. He contributed to the journals occasionally, and to the Liverpool Medical Institute, of which he had been president. In 1884 he reported the successful treatment of bronchocele by hydrofluoric acid, and further cases in 1888.

Dr. James P. Drinkwater died yesterday, in his 78th year, at Llangollen, where he had been medical officer to the Town Council for above forty years. He held other offices in the county. In early days he had served as surgeon on the North American Mail S. S. Co. He took his M.B.C.S. in 1852.

Dr. Charles E. Dumbleton, formerly Health Officer at Singapore, and surgeon at Dolby Hospital, Queensland, was a patient at St. Thomas' Home, suffering from gout. On Wednesday morning he was missed from his bed and found hanging from a rope, dead. He was 46 years of age. A Cambridge graduate, M.A. 1884, M.D., 1891. He had been Assistant Medical Officer in the Coton Hill Asylum, and also House Surgeon to the London Temperance Hospital.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

THE BRITISH MEDICAL ASSOCIATION MEETING—CANADIAN ASSOCIATIONS—A GOVERNMENT LUNCHEON—FIRE AT QUEENS MEDICAL DEPARTMENT—AMERICAN ORTHOPEDIC ASSOCIATION MEETING—INFANT MORTALITY PLAINLY DISCUSSED.

THE attendance at the recent meeting of the British Medical Association at Toronto surpassed all expectations. The fact that in the number of members registered it was the second largest meeting in seventy-four years of the Association's existence, is satisfactory evidence that the Canadian organization left nothing undone to make the meeting a success. The number of Canadian medical men who registered their membership and attendance was 1,103. The total registration of medical men at the meeting was 1,938. To this number may be added nearly three hundred Canadian medical students. The papers and discussions in all the sections were of a high order, and from a scientific point of view the Association has never had a more satisfactory meeting. The large attendance of medical men from the United States, who were warmly welcomed as visitors, was most gratifying. There were over three hundred ladies among the visitors. The local committees did their work well, and to the complete organization must be attributed a large measure of the success of the meeting. The financial management must have been excellent for the executives are now able to report that notwithstanding the large expenditure in connection with the local arrangements, there was still a small surplus left.

The annual meetings of the Canadian and Ontario Medical Association were held at Toronto the day preceding the opening of the British Medical Association. No business was transacted, and the officers of each Association remain the same as for the past year. The Canadian Medical Association will meet in Montreal next year, and the Ontario Association in Toronto.

One of the many pleasant entertainments at Toronto

during the recent meeting of the British Medical Association was a luncheon given by the Government of Ontario to the members of the section in psychology. This section was largely attended by medical men from Great Britain, United States, and Canada, specially engaged in the care and treatment of the insane. The luncheon was given at the Toronto Hospital for Insane. Among the speakers on the occasion was the Hon. W. J. Hanna, Provincial Secretary for Ontario, with whose department are associated all the hospitals and public charities of the Province.

The Medical College building in connection with Queens University, Kingston, was destroyed by fire recently. Although there was an insurance of only $22,000, steps were immediately taken to erect a new building, which it is expected will be ready for use early in October. The fire, it is thought, originated from a gas jet kept burning in an oven where paraffine molds were made. This fire is the first to visit Queens in its history on the present grounds. Four years ago an extra story was added to the building, at a cost of $11,000. The destruction of the bacteriological and public health laboratories in connection with the college, will for the present cause considerable inconvenience.

The annual meeting of the American Orthopedic Association in Toronto on August 20 to 23, was well attended. Afternoon and evening sessions were held for the discussion of scientific papers. An interesting feature of the meeting was the exhibition of apparatus and the presentation of clinical cases. Several pleasant social functions were held in honor of the visiting guests.

The question of infant mortality in Canada has been attracting considerable attention lately, and a recent statement, made by the Secretary of the Provincial Board of Health of Ontario, has excited much comment. In Canada, as in the United States, there are doubtless thousands of women whose sole aim in life is to have a good time socially, and to avoid maternity. If they do become pregnant they make the most desperate efforts to rid themselves of the products of conception. Failing in this they do not nurse their babies, and these, therefore, have reached a high death rate. The Provincial Board of Health is generally commended for preparing and issuing instructions for use of mothers. The vigor shown in some of these instructions may be illustrated by the following quotation from the Secretary's report: "It is time we reverted to the old-time idea, that the destruction of the young life, at no matter what stage in its development, except for well-grounded reasons, results disastrously to the mother, and is as criminal on the part of those who participate in it as it is demoralizing to our social life. If our Canadian race of women were rickety and destitute, as are many of the women found in the crowded and poor centers of Europe, there might be some excuse for this silent slaughter of the innocents, but in my opinion such extenuating circumstances cannot be generally advanced. Hence, it is with feeling of regret I direct the attention of this Board to the facts just submitted—with the hope, however, that in directing public notice thereto something may be done to correct this evil, which works with a malignance as subtle and yet as certain in its results and as fatal as any disease known to the physician or surgeon, and what is still worse, is demoralizing to the State."

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

DECREASE IN THE NUMBER OF CHOLERA CASES—INFECTION THROUGH VEGETABLES—SPREAD OF THE DISEASE TO OTHER SEAPORTS—ARMY MEDICAL BOARD FOR THE STUDY OF TROPICAL DISEASES—PERSONAL NOTES.

MANILA, P. I., July 31, 1906.

DURING the past three weeks cholera in Manila has been steadily diminishing. In view of the fact that this is the season of the year at which, in former times, the disease prevailed to a greater extent than at any other period, the fact that it has not been increasing, and that during the middle of the month it was at a standstill, and that it is now actually decreasing, makes the outlook for the cholera situation in Manila very encouraging. During the month of July there were 394 cases with 349 deaths in Manila, and 2,199 cases with 1,591 deaths in the provinces. The largest number of cases reported for any one day in Manila, during July, was on the third, when 32 cases were reported. On the Fourth of July there were 28 cases. The nearest approach to this number occurred on the ninth of July, when there were 24 cases, and since that time there has been a steady decline. Upon the twenty-ninth of the month there were no cases reported; however, the next day, July 30, eight cases occurred in the district of Tondo.

As the epidemic advances, it is becoming more and more apparent that the major portion of the infection is, in all probability, in that class of vegetables which are ordinarily eaten raw, and which have been fertilized with human excrement to which has been added some cholera stools. The police, the detective department, and the force of the Bureau of Health are all cooperating in an endeavor to locate the places where these vegetables are grown, in order that the guilty parties may be prosecuted and the nuisance abated. They have, however, been fined so often in the past on account of this practice that they have become extremely wary, and detection has become extremely difficult.

Within the last ten days the disease has spread to the province of Tayabas by the road which has recently been opened from Bay, Laguna, to Lucena. The seaports of Pagbilao and Lucena are infected. This feature of the situation is rather discouraging, because it will be impossible to maintain as efficient an outgoing maritime quarantine at the foregoing ports as it has been possible to maintain at the port of Manila during the past year, hence there is great danger of the disease spreading to the southern islands. On this account the Bureau of Health is making extraordinary efforts to stamp out the disease in the seaports and gradually drive it back to the territory which it has heretofore occupied. If the cholera should be conveyed to some of the nearby islands, it will, in all probability, spread throughout the Philippines, and the experience of the epidemic of 1902 will be repeated. The health officials feel that if the disease can be confined to the island of Luzon, at points which are readily accessible from Manila, that the chances of eradicating it within a year are good; on the other hand, if the disease must be combated in many different islands, to which access is exceedingly difficult, it may be a number of years before the Philippines can be finally freed of this disease.

During the month cholera again made its appearance in Bilibid prison, but the vigorous disinfecting measures which were instituted by the Bureau of Health stamped out the disease in a few days.

The Army Medical Board for the study of tropical diseases, which is composed of Assistant Surgeons James L. Craig and Percy M. Ashburn, is now undertaking the study of the etiology of dengue. In addition to this work, they will also proceed in a few days to Iloilo, for the purpose of ascertaining whether surra can be conveyed from carabaos to horses by artificial means.

The plague at Hongkong, which during the month of May reached the high number of 116 cases per week, is now steadily declining. For the week ended July 21 there were 7 cases reported. Since January 1 there have been a total of 875 cases, with 818 deaths. Of these, 854 cases with 803 deaths occurred in Chinese persons; 6 cases with 3 deaths among Europeans, and 15 cases with 12 deaths among other Asiatics, who were principally Japanese.

Dr. Harry T. Marshall, who was formerly connected with the pathological laboratory of the Johns Hopkins Laboratory, has arrived recently in Manila and accepted the position of pathologist with the Bureau of Science.

Dr. C. T. Hibbett, surgeon of the U. S. Navy, who has been in command of the Naval Hospital at Canacao, Cavité, during the past two years, has completed his tour of duty in the Philippines and has been ordered to return to the United States. Surgeon Nash, who was on duty on the *Rainbow*, the flagship of the Philippine squadron, has succeeded Dr. Hibbett in command of the hospital.

Progress of Medical Science.

New York Medical Journal, September 1, 1906.

Typhoid Infections of the Appendix.—Maynard A. Austin says that a simple appendectomy is usually all that is necessary in early typhoid cases, and when death occurs it is usually due to some later complication of the typhoid fever, and not from any immediate result of operation. He reports two cases in which there arose the question of diagnosis of typhoid fever and appendicitis which might seem easy to solve from the usual source of infection, until one had had the experience of being called in to distinguish such conditions.

Electrolysis in the Treatment of Deafness Due to Stricture of the Eustachian Tubes.—David G. Yates states that two symptoms are prominent in stenosis of the Eustachian tube, deafness and tinnitus. He reports four cases in which the indication was plain, to render pervious the Eustachian tube, and with one exception this was done with the bougie. After a brief description of the technique of the procedure, he states

that the main elements of success with this method are time and patience. The results are generally satisfactory and often brilliant.

Is Nervous Dyspepsia a Disease Sui Generis?—Achilles Rose believes that many cases diagnosticated as hysteria, neurasthenia, or nervous dyspepsia are nothing more than manifestations of atonia gastrica. The three flat abdominal muscles control to some extent the secretion, the circulation, and the innervation, as well as the position of the abdominal viscera. When the abdominal wall becomes atonic these organs sink, and such ptosis is conducive to many pathological conditions. In such cases abdominal plaster strapping relieves this relaxation. When abdominal support relieves the symptoms of so-called nervous dyspepsia, one has a scientific foundation for therapy. In numerous publications the abdominal belt for the relief of gastropsia and the mode of application are fully described.

Journal of the American Medical Association, September 8, 1906.

Postcritical Fever and Other Sequels of Pneumonia.—J. E. Talley reports cases of a number of conditions giving rise to febrile symptoms, after the crisis of croupous pneumonia, including among them empyema, abscess, endocarditis, and pericarditis, relapsing pneumonia, pleurisy, bronchitis, otitis media and meningitis, parotitis, hemorrhagic nephritis, thrombosis, neuritis, and colitis. The causes, therefore, he concludes, are manifold, and are often revealed only after careful and repeated examinations. Even if such examinations are apparently negative, one should be slow in attributing the fever to delayed resolution or to autolysis alone. More often, he thinks, a varying persistence of a purulent tendency, especially in the stage of gray hepatization, will explain the fever. Minute abscesses, hard to detect, or even a single one, may be responsible. The *x*-ray, he states, is of rather doubtful value in detecting such conditions; a thickened pleura embarrasses this means of diagnosis. The reported cases of cardiac complications in the paper hardly indicate the real importance that should be attached to this cause as a factor in many fatal cases. One should always be on the alert for this complication, especially in patients who have an old endocarditis or atheroma. The right side of the heart, as his cases show, is not always uninvolved. The development of a systolic murmur may be explained by anemia or muscular weakness, but the development also of a diastolic murmur usually means genuine endocarditis.

Incurable Eyestrain.—G. M. Gould remarks that there is little mention in the text-books of the important class of incurable eyestrain cases, and insists on the necessity of their recognition, for the information both of the patient as to his limitations and of the physician in his management of the cases. It is bad enough, he says, that thousands of patients should be gastrologized, laryngologized, gynecologized, etc., for easily curable eyestrain, but it is far worse when the eyestrain is incurable. He includes the causes of irremediable eyestrain under the following heads: congenital anomalies; high degree of ametropia; sequels of inflammatory disease, traumatism, amblyopia or other injury of ametropia, chronic heterotropia, cerebral or neural disease, systemic disease or diseases of interrelated special organs, injurious occupations, and unhygienic uses of the eyes. Under each of these heads the special causes are noted. The paper is an interesting one, and full of instructive details.

Internal Antiseptic Treatment of Tuberculosis.—H. H. Mahone proposes an antiseptic treatment of tuberculosis. The drugs he would employ are iodine and phenol, the latter lessening the irritating action of the former and permitting the use of larger doses. Both, he claims, also promote constructive metabolism under proper conditions. The formula which he has himself successfully used is given as follows: Phenol and tincture of iodine, each 160 minims; spirit of camphor, 3½ drams; glycerin, ½ ounce; and equal parts of cherry-laurel water, cinnamon water, chloroform water, and tar water to make 15 ounces. Mix and allow to stand until all free iodine disappears. Then make an emulsion by adding one ounce each of cod-liver oil and powdered acacia. Begin by giving one teaspoonful in ½ cup of water every four hours and gradually increase the dose to a tablespoonful at one hour intervals.

Femoral Herniotomy.—A. J. Ochsner claims that all that is required in treatment of femoral hernia with the normal circular opening of the femoral canal is to dissect out carefully the hernial sac quite up into the peritoneal cavity beyond the inner surface of the femoral ring, ligate it high up, cut it off, and permit the stump to withdraw within the peritoneal cavity. Removing all the fat contained in the femoral canal and simply closing the skin wound completes the operation. The method is based on the well-known fact that it is practically impossible to keep a circular opening in any part of the body from closing spontaneously unless it be lined with a mucous or serous membrane. In cases where the opening is congenitally not circular or is torn in traumatic hernia, or is cut in strangulated cases, this method is of course not indicated. He has used this method constantly for fourteen years and finds that, barring unusual accidents, recurrences do not happen. He tabulates the cases thus operated on from which he has been able to obtain definite reports, thirty in number, and in none of these was there a recurrence. He reviews the principal features of the more important methods used in femoral hernia, some of them in detail, and concludes that every one of them that does not utilize the principle here emphasized of leaving the femoral canal in the form of a circular opening, is faulty.

Filigree Reinforcement of Abdominal Scars.—W. Bartlett finds that a scar, no matter how thin, if kept from stretching by imbedded wires, forms a reliable integral portion of the abdominal wall, and that a ready-made filigree answers all the requirements. Since scars tend to stretch laterally, the filigree need be made up only of cross wires, held together in the middle by a single twisted strand following the line of the suture. His operative technic is described. He dissects away the old scar in postoperative hernia cases, opens up the sac, and with the hand inside dissects it away from the abdominal wall, separating the peritoneum and transveralis fascia from the posterior surface of the muscles, trimming it and closing it, and on the bed thus formed by fascia the filigree is placed and held by sutures at its extremities. It does not matter if, the defect being large, it is impossible to reunite the edges of any structure by the skin; all that is needed is that the edges of the network be covered for a short distance. He is convinced that a segment of the abdominal wall, consisting of peritoneum, filigree, and skin, is sufficient, provided the operation has been properly done. Cases are reported showing how well the contrivance works in various conditions; suppurating wounds, pregnancy, as a prophylactic arrangement, etc. He has had no failures to record in his five years' experience.

The Pathology of Bile.—W. Salant reviews the literature as to the changes observed in the bile in various pathologic conditions. It is decreased in febrile states, apparently more from functional derangement than from structural changes of the liver. It seems also to be diminished in malignant disease. The pigmentary changes have been considerably noticed and a wide range of variation in color has been observed in certain forms of disease. If the enterogenic origin of urobilin from bile pigment is accepted, its presence in large quantities in the urine in so many diseased conditions may serve as a proof of the increased formation of bile pigments in disease. Abnormal constituents of bile have been determined in various pathologic conditions, such as dextrose, urea, albumin, etc. Albuminocholia has been observed in cloudy swelling of the liver of pneumonia, tuberculosis, and sepsis, in various experimental intoxications, etc., but the subject does not appear to be fully cleared up as to the origin of the albumin, whether it is eliminated by the liver or due to inflammation or irritation of the gall bladder and passages. The toxicity of the bile in pathologic conditions is noticed. Pouchet claims to have isolated the poison of toxic bile in cholera and finding it in the nature of a pyridin base. Meltzer and Salant have found the toxicity of the bile increased after double nephrectomy, the exciting element predominating.

The Lancet, August 25, 1906.

Sterile Caseous Matter in the Treatment of Tuberculous Disease.—Peter Paterson makes a preliminary report of observations made on the effect produced in tuberculous lesions by the injection of some of the products of the tubercle bacillus as elaborated in the body, and reports five cases which, though by no means conclusive, are at least encouraging and justify further investigation. If tuberculous pus be kept in a refrigerator five or six months, but allowing it to thaw frequently during that time, the pus will not induce tuberculosis when injected into guinea-pigs. Having thus destroyed

the bacilli by this means, the serum is poured off and the sediment is then washed for three days in a continuous stream of cold sterilized water to remove all soluble toxins. Sterile normal salt solution is now added to the fine white sediment till each cubic centimeter of the emulsion contains five milligrams of solid substance, and the material is ready for use.

An Anti-Cholera Serum.—Allen Macfayden draws the following conclusions from his experiments: 1. That acutely toxic cell juices possessing active immunizing properties can be obtained from the cholera organism by the method employed. 2. That an antibody can be produced for that primary poison which exists as an integral constituent of the cholera bacillus—a matter upon which there have been considerable dispute and difference of opinion. 3. That the antiendotoxic power of the serum can be raised to a marked degree—a matter of equal importance. 4. That the serum in addition to its antiendotoxic possessed agglutinative and bacteriolytic properties. 5. That in the case of the cholera organism there exists an intimate relationship between its virulence and toxicity. 6. That the cholera endotoxin obtained under the conditions described is thermolabile, being readily destroyed at 55° and 60° C.

British Medical Journal, August 25, 1906.

Muscle Plasma; Its Opsonic Power and Function in Phagocytosis.—R. W. Allen writes that the action of opsonins being upon the bacilli and not upon the leucocytes, there is no objection to the employment of white blood cells of man in estimating the opsonic index of rabbit's blood serum or muscle plasma, the method of Wright being employed. In using rabbit's blood cells very few if any polymorphonuclear cells with bacilli inside were usually to be seen; such as were seen were in a very damaged condition, and the contained bacilli were undergoing solution, whereas the nonphagocytic white cells seemed perfectly healthy. It would appear that tissue plasma has a definite lytic action upon leucocytes which have taken up organisms, whereas it is without effect upon the normal white cells. The slow breaking down of leucocytes and their contained organisms would probably result in the formation at some period of powerful toxins, and it is possible that the rôle of this constituent of muscle plasma is to carry the process rapily past this period of danger.

Fissura Abdominalis and Double Genitalia.—Edwin Chill reports the case of an eight months fetus who lived for some hours after its birth. The whole of the abdominal wall was absent from about an inch below the point of the sternum to within an inch of the pubic bone, with the exception of a small irregular flap of skin which contained the umbilical cord. The viscera protruded and there was no great omentum. The external genitalia were duplicated and separated from one another by a clearly defined central space of skin. The urogenital and anal orifices on both sides were extremely rudimentary. There were present two shallow sinuses, with raised labia majora in each and two anal depressions below the perineum on either side. With the exception of these abnormalities the child was in every respect well formed, and cried lustily at birth.

Scleroma Neonatorum in Twins.— Bertram Addenbrooke reports these cases occurring in twins, a boy and girl with separate placentæ, who were apparently quite strong and healthy. Two days after birth he found the feet of the little girl very much swollen, hard, and waxy, pitting on pressure; the child was somewhat somnolent and refused the breast; the temperature was 97°, and the pulse 90. The swelling rapidly spread up the legs and thighs to the middle of the abdomen, and by the morning of the next day it involved the head and upper extremities. On this day the same condition was noted in the boy. The girl died on this, the third day after birth, and the boy three days later.

Berliner klinische Wochenschrift, August 20, 1906.

Syphiloma of the Internal Organs of the New Born.—Babes and Mironescu discuss this question with reference to its association with the *Spirochæta pallida*. From their studies on congenital syphilis the authors advance the claim that even in the newly born the internal organs become involved in the form of a nodular process and that there are cases in which the general diffuse lesions are absent while the neoplastic form of lesion is very well marked. It seems possible, therefore, to differentiate three forms of congenital syphilitic lesions: (1) a diffuse type, which either involves all the organs or only a few, (2) another in which circumscribed nodules in one or more organs appear and in which there are only slight generalized lesions, and (3) mixed forms in which both the circumscribed and diffuse lesions are present. Two cases are reported in which this nodular tissue proliferation occurred, including the parenchyma, and these processes seemed to be in intimate relation to the proliferation of the spirocheta. While this was well marked in the nodular form of the disease, it was absent in the diffuse type. When found it seemed that the number of bacilli was in direct proportion to the extent and severity of the syphilitic process, and in one of the cases they were localized in the hepatic capillaries.

Metastasis in Transplanted Sarcoma.—Haaland presents the results of his observations in mice. Ehrlich and Apolant have shown that a sarcomalike tumor is sometimes found developing on a transplanted carcinoma in the mouse which has all the characteristics of a true neoplasm. Haaland calls attention to the fact, however, that one of the principal characteristics of a malignant growth, namely the ability to produce metastatic deposits by cell embolism, has never been demonstrated. Accordingly, he studied the question from this standpoint and found that in a considerable number of cases (14 out of 23) pulmonary metastases could be shown without difficulty. They existed in the form of minute emboli of cells in the smallest pulmonary arterioles and in their later development showed the same tendency to infiltration of the surrounding region which is characteristic of the cells of the parent growth, the vessels being perforated and the parenchyma involved. This results in the formation of nodules of which the stroma is but little developed. Metastatic deposits in the lymphatic glands have also been noted, as well as in the liver, although in the latter it could not be demonstrated whether the emboli gained their way into the organ through the hepatic artery or the portal vein. This is to form the subject of a future investigation.

American Journal of the Medical Sciences, August, 1906.

Vascular Tension in Chronic Illness.—Hobart Amory Hare gives the following summary of the points which he emphasizes in his paper: Cardiovascular stimulants are often given when vascular relaxants are really needed. More attention to the protection of the heart from unnecessary labor is advisable. If the physician will direct his treatment to the vessels the heart will often be able to care for itself. A heart should not be stimulated to increased effort when the real object is to decrease its burden and to diminish the toxemia which is destroying its function.

A New Intestinal Parasite of Man: Paramœba Hominis.—Charles F. Craig describes this parasite, which he has observed in the feces of six natives of the Philippine Islands. The only symptom of importance in five of the cases was diarrhea. The stools were of watery consistence and in three instances contained a little blood and mucus. In only one case was *Entamœba dysenteriæ* present. Unlike any other ameba hitherto described as infecting man, this specimen undergoes a flagellate and an ameboid stage of development. The writer has not been able to demonstrate reproduction by longitudinal division during the flagellate stage of growth. However, he believes that such a method of reproduction probably occurs, and he thinks that this organism may be properly placed in the genus *Paramœba* described by Schaudinn. He is not prepared to speak concerning its pathogenicity. The parasite has thus far been found only in natives of the Philippine Islands.

The Relations of Chronic Villous Polyarthritis to the Dumbbell-Shaped Bacilli.—Max Schueller has demonstrated in one hundred and fifty out of two hundred and thirty cases of chronic villous polyarthritis the presence of dumbbell bacilli. Cultures were made from aseptic punctures of unopened joints with a special puncture needle and also from all of the writer's operated cases. He declares after repeated inspection of many microscopic preparations of slices, cultures, dry cover-glass specimens, taken from patients as well as preparations taken from joints, and blood-cultures from animals, that the name he has given to the bacillus causing polyarthritis chronica villosa in the joints, although not conspicuously adaptable to every specimen, characterizes undoubtedly in the greater majority of instances the form of the bacilli. He therefore believes that the name "dumbbell-shaped bacilli" should be retained exclusively for the bacilli of polyarthritis chronica villosa. He is convinced that this affection is caused by this bacillus alone, and that it has no near etiological relations to acute rheumatic arthritis.

Peptic Ulcer of the Esophagus.— Wilder Tileston states that in a large proportion of cases the ulcer has not been suspected during life. It is either entirely la-

tent or gives rise to no symptoms sufficiently characteristic for a diagnosis. The most prominent manifestations of the stage of ulceration are pain, dysphagia, vomiting, hematemesis, and perforation. The diagnosis of peptic ulcer of the esophagus is difficult and in many cases impossible. However, in some cases it may be made with considerable certainty. It is practically certain if other causes of ulceration can be excluded, and there are dysphagia, pain during or soon after deglutition, situated under the sternum or between the shoulder-blades, hematemesis or melena, and obstruction in the lower part of the esophagus. Symptoms of present or past ulcer of the stomach or duodenum offer valuable confirmatory evidence. The prognosis is grave. In the stage of ulceration the indications for treatment are the same as in the case of gastric ulcer.

A Case of Narcolepsy.—Albert N. Blodgett reports this case. The direct ancestor in the third generation antecedent to this patient was afflicted with an acquired infection of specific character. As far as is known the direct offspring of this ancestor all suffered from stigmata referable to direct inheritance. In these patients the disease appeared in the form of affections of the nervous system. The inherited taint appeared in the members who survived childhood only after full maturity. Narcolepsy is not often fatal. The writer presents a family chart and gives a brief history of the various members of this family.

An Unusual Case of Antitoxin Rash.—Ray Lyman Wilbur gives an account of this patient, who had a strain of Spanish blood. During childhood she was an asthmatic. There was also a history of occasional urticarias following the eating of strawberries or shellfish. As a member of the family was ill with diphtheria, this woman was given an injection of a thousand units of antitoxin. This was followed by an intense reaction almost immediately. The heart-beat became rapid, forcible, and inefficient. The mucous membranes became temporarily edematous. By much encouragement and the exertion of great will-power consciousness was retained. The patient thought that she was about to die. Hot black coffee improved the cardiac action. A severe asthmatic attack followed the first period of partial collapse. For thirty-six hours there was great anguish from the intense itching and burning of the skin over the entire body. Besides the hyperemia of the skin there developed immense white wheals. During the second day the rash rapidly subsided. The suddenness of the attack suggests that the effect of the antitoxin may have been upon the central nervous system, producing, perhaps, a peripheral vasomotor paralysis. Since this attack the patient has been quite well.

Hematogenous Albuminuria.—R. Hingston Fox, after referring to the history, nomenclature and causes, states that the three chief signs of hematogenous albuminuria are (1) the albumin is absent or at least lessened in the night urine; (2) it disappears after taking calcium lactate, and (3) the urinary sediment contains no casts or renal cells, but often crystals of uric acid or oxalates. Many years' experience is needed to decide with certainty whether these cases eventually become the subject of progressive kidney disease. So far the evidence suggests that we need not take a serious view of this disorder. Rest in bed, a milk diet, saline purgatives, iron and nux vomica—tonics for the blood and nervous system—were used long ago and cured the disorder. The direct use of calcium lactate gives a new and effectual means of altering the blood state on which the transudation of albumin depends. When the albuminuria is refractory to the calcium salt he advises trying the strontium lactate.

French and Italian Journals.

Pigmentary Mask.—Gilbert and Lereboullet have observed in chronic asystolics the pigmentary mask more or less accentuated. This discoloration is more marked on the forehead and on the temples. The mask is due to cholemia, a consequence of passive hepatic congestion. Reference is made to several cases. The first patient had passed through two pregnancies without such discoloration. The mask which appeared at the time of the attack of asystole became accentuated by the repetition of the crises. Cholemia was intense, urobilinuria marked. The mask grew lighter after the passing of the crises and the cholemia. The second patient had never been pregnant. The mask appeared on the occasion of a mitral asystole, with cholemia, urobilinuria, and objective liver symptoms. In an asystolic, the appearance of this mask points to the presence of hepatic congestion with cholemia.—*Le Progrès Médical*, June 30, 1906.

Aneurysms of Large Vessels: Etiology, Pathogenesis, and Treatment.—Lancereau states that the aneurysms of the large vessels, those of the aorta in particular, commonly result from the action of the microorganisms of the three diseases, tuberculosis, syphilis, and malaria. These microbes localizing in certain cases in the external coat of the arteries cause the formation of young connective tissue elements. Sometimes they penetrate to the middle coat, which they perforate. The lessened resistance of the arterial wall under the influence of blood pressure ends at times in a hemorrhage, sometimes in an aneurysm. Preventive treatment consists in combating the alteration of the blood-vessels. For this purpose the employment of mercurial and iodine preparations is indicated in syphilis. Such treatment is also useful in aortic sclerosis of malarial origin, at least in the beginning. When the aneurysm is once formed the physician can practise ligature of the vessel. Not only, however, is such a ligature dangerous, but it is impossible when the aneurysm involves a large vessel, the aorta in particular. In such cases coagulation of the blood should be favored in the aneurysmal pocket. Lancereau and Paulesco have had distinct success in a large number of cases with injections of gelatinized serum. Such preparations should be perfectly sterilized. In 1,200 injections Lancereau reports that there has not been one accident.—*La Tribune Médicale*, June 30, 1906.

Mechanism of the Action of Diuretics.—Giuseppe Matucci has made a study of the causation of diuretic phenomena in animals by section of the medulla at various levels and injections of glucose after the section. He believes that he is in a position to deny the existence of a center for the secretion of the urine in the medulla. The author then separated the kidney from all its nervous connections and made sections of the medulla. He denies the existence of a center between the third and fourth cervical vertebræ on which diuretic substances act. There is a constant relation between blood pressure and secretion of the urine; although he does not think that the secretion is entirely dependent on pressure and would not exclude a secretive action of the renal epithelium, still the main factor in secretion seems to be blood pressure. The composition of the urine supports this argument, because were the increase in quantity due to increased functioning of the epithelium the solids should be increased, while in fact the water is much more increased.—*Lo Sperimentale*, LX. year, Vol. III.

Repair of Nerve Fibers.—M. Segale, in order to establish the method of regeneration of the nerve fibers in an animal which has been paralyzed as a result of secretion of a nerve and has recovered from the injury, examined many cases of such recovered nerves. He believes that autoregeneration takes place of the nerve fibers. He found nerve fibers in the cut portions of nerves shaped like a key. There were also ramifications of nerve fibrillæ in the substance of the muscles about the cicatrix. The author has never been able to demonstrate new formed nerve fibers in the peripheral segment of the nerve, as long as it remained separated from the central fragment. The new nerve fibers in the peripheral segment arrive there by roundabout ways from the center.—*La Riforma Medica*, June 23, 1906.

Fatty Cyst of the Transverse Mesocolon.—G. D'Urse reports a case of fatty cyst of the mesocolon, an unusual location for such growths, which are usually connected with the small intestine. The cyst gave no symptoms, the ones for which the patient came to the author being those of an ordinary indigestion. A tumor was felt in the abdomen which was supposed to be connected with the stomach, and a laparotomy was advised with the diagnosis of myoma of the gastric wall. The tumor proved to be in the mesentery of the transverse colon instead of in the wall of the stomach. It consisted of a cyst with fibrous wall containing a thick fatty fluid, the microscopic examination of which showed it to be an emulsion of finely divided fat globules with no cellular elements. The histological examination of the cyst wall showed it to result from changes in a lymphatic gland of the mesentery. Such cysts may be serous, chylous, echinococcic, or epithelial in their nature. This one was evidently chylous. We cannot speak of true chylous cysts of the colon, but experiments on animals show that a certain amount of fat may be absorbed by the wall of the colon, and this probably arose in that way, the fats being carried by the lymphatics to this gland, where from occlusion of the lymphatic vessels the contents were retained and formed the cyst.—*Il Policlinico*, June, 1906.

Book Reviews.

PRACTICAL MEDICINE SERIES. Edited by Dr. GUSTAVUS P. HEAD, Chicago. Vol. III: Eye, Ear, Nose and Throat. Chicago: The Year Book Publishers, 1906.

THIS series of annual reviews has firmly established itself in the estimation of American practitioners. In this volume Dr. Casey A. Wood reviews the literature of the eye, D. Albert H. Andrews that of the ear, and Dr. Head that of the nose and throat. No attempt is made to collate all the articles of the year on each topic but careful analysis is made of all that are in any degree noteworthy. The wheat is thus winnowed from the chaff. The book is well printed and freely illustrated. The index is full and is accompanied by a list of authors quoted.

TRACHOMTHERAPIE IN DER VERSEUCHTESTEN GEGEND UNGARNS. Von Dr. MARCZEL FALTA, Augenarzt in Szeged. Redigiert von Sanitätsrat Dr. MAX OHLEMANN, Augenarzt in Wiesbaden. Berlin: S. Karger, 1906.

THIS brochure, which is one of 104 pages, with a few illustrations in the text, purports to be a presentation of all that is really known about trachoma as regards its various forms, the methods of treatment of the disease and the results of the disease. A description of the affection occupies four and one-half pages. The rest of the volume, with the exception of three or four pages which are devoted to a description of the examination of trachomatous patients, is taken up with the question of therapy. The subject is a trite one, but the author has handled it in such manner that he has produced a volume worthy of the perusal of those who are interested in the study of this disease.

THE DAMASK GIRL, and Other Stories. By MORRISON I. SWIFT. New York: The Morrison I. Swift Press, 1906.

THIS is a little volume of 144 pages, and contains nine short stories. The nerve specialist in the second story was certainly "A Very Rash Doctor," and if that story is a sample of the hero's powers as an expert witness, we can understand the disrepute in which that class is held. In "The Scientist's Wife" we see some of the possible complications, when a man is attached to science by one hand and to a jealous wife by both hands. The book will take but little room in the holiday seeker's valise, and will blend well with a hammock, a fan, a pipe, and a snooze on a warm afternoon.

NOMENCLATURE ANATOMIQUE EN QUATRE LANGUES, par le Dr. PAUL RODET. Paris: Masson et Cie., 1906.

THIS is a list of anatomical terms in Latin, French, English, and Esperanto. The Latin is that of the nomenclature adopted by the Congress of Basle; the French is that of France; the English is, usually and with an occasional hiatus, that of English-speaking anatomists; the Esperanto is, we assume, that of the Esperantists. The latter looks to the uninitiated easy enough, but ugly. The accessory thyroid glands may be called "gl. thireojdaj akcesoraj," if one wishes, but we think the Latin term will be more generally understood, and it certainly rolls off the tongue more easily. However, if one has the curiosity to know the Esperanto equivalents for the good old English, or the more solemn and international Latin terms, he will find them here. The vocabulary is especially valuable in supplying a list of the Basle anatomical terms and their equivalents in French and English, but its utility would have been increased by the inclusion of the Italian (which are not always the same as the Latin, even allowing for the regular modifications of termination) and the Greek terms.

MANUAL OF ANATOMY, Systematic and Practical, Including Embryology. By A. M. BUCHANAN, M.A., M.D., C.M., F.F.P.S. Glas., Professor of Anatomy in Anderson's College, Glasgow; Examiner in Anatomy for the Triple Qualification of the Scottish Licensing Bodies; Examiner in Anatomy and in Physiology for the Dental Diploma, and Examiner in Anatomy (Human and Comparative) for the Fellowship of the Faculty of Physicians and Surgeons of Glasgow; ex-Examiner to the University of Glasgow; formerly Senior Demonstrator of Anatomy in the University of Glasgow. Vol. I., Osteology; Upper Limb; Lower Limb. With 268 Illustrations, mostly Original and in Colors. Chicago: W. T. Keener & Co., 1906.

THIS is the first volume of a new work on Anatomy designed especially for the student. The author has had a long experience as an examiner in this subject, and in preparing the treatise has kept the examinational requirements of the candidates for the medical or surgical degree constantly in view. The result has been, as far as we can judge from this first volume, very satisfactory from the student's standpoint. The volume is handy in size, with limp covers, and so offers a convenient manual for dissection; the description of the various parts is succinct and clear, and the illustrations are in the main excellent. For the requirements of the student, in his student days, we should say Dr. Buchanan's work is perfectly adequate, but it has one fault—a virtue in most works, but not in anatomies—that, namely, of conciseness. A treatise on anatomy is an essential for the practitioner's library, one to which he must refer constantly (for who remembers the details of anatomy?), be he internist or surgeon, and in this reference he needs especially details rather than broad facts. Compared with the two standard works, Cunningham and Gray, this otherwise most commendable treatise is deficient in this very insistence upon minute and apparently unimportant details; it supplies fully and completely all that the student needs to enable him to pass a creditable examination, but it is inferior to the two books mentioned as a work of reference for the library of the practitioner who has to grapple with disease and needs all the aids that books can furnish to enable him to diagnose and treat with success all the ills that flesh is heir to. As a preliminary work, however, if one can conveniently add works of reference to the essential library of his student days, Dr. Buchanan's can be conscientiously recommended.

ABBOTT'S ALKALOIDAL DIGEST. A Brief Description of Some of the Principal Alkaloidal medicaments, with Suggestions for their Clinical Application, and Embodying Various Articles on Important Special Agents and Certain Great Phases of Alkaloidal Therapy that Have Been Developed in the Personal Practice of the Author and His Colleagues. By W. C. ABBOTT, M.D., Editor of *The American Journal of Clinical Medicine*.. Chicago: The Clinic Publishing Co., 1906.

THE scope of this little manual is fully described on the title page, and we can only say that the contents meet the description in every particular. The author is one of those cheerful souls—the therapeutic optimists—all too rare in the recent past, but now happily growing more numerous, who believe in the power of drugs, judiciously administered, to arrest or modify the course of morbid processes, even those of the so-called self-limited diseases. The book is frankly a missionary tract of the alkaloidal therapeutists, but it nevertheless contains much that will be found useful, even by the nonbeliever in this special form of medication.

LES EMBOLIES BRONCHIQUES TUBERCULEUSES. Etudes Cliniques, par le Dr. CH. SABOURIN, Directeur du Sanatorium de Durtol (Puy de Dome). Paris: Felix Alcan, 1906.

IN this treatise the author has for his object the distinction between primary tuberculous lesions of the lung, and secondary lesions of the same organ having their origin elsewhere. The primary lesions are nodular; the secondary lesions are tuberculous pneumonias. It is the secondary pneumonic type that the author places in bold relief, and to which he assigns a special pathogenesis. Tuberculous pneumonias, or pleuropneumonias, which are often necrotic, have for their immediate cause a bronchial embolus (this embolus being the product of bacilli) which has traveled from some primary nodular focus in the lung. They in no way differ from ordinary infarcts, save in their bacillary origin, and have a marked tendency to terminate in necrosis, suppuration, and cavity formation. The causation of these emboli, and the great fact that dominates their tendency to necrotic tuberculous pneumonia and decides its extent and subsequent prognosis and treatment, is that the lesion follows upon fatigue and exhaustion from overwork or excesses and overexercise, and the author believes that no tuberculous individual who submits to rational hygienic treatment from the first appearance of the infection ever goes into the stage of secondary pneumonia of necrotic type. These opinions are based upon a series of clinical observations and close study, and the author asserts that when incipient primary cases are treated in sanatoria where they are compelled to lead quiet, rational, hygienic lives, they never terminate in tuberculous necrotic pneumonias with their subsequent foci of suppuration and cavity formation. The last chapter of the book is devoted to the signs and symptoms of tuberculous pneumonias occurring along the interlobular tissues and involving the pleura between the lobes of the lungs. The book is carefully written and can be heartily recommended as worthy of study.

AIDS TO SURGICAL DIAGNOSIS. By H. W. CARSON, F.R.C.S., Surgeon, Tottenham Hospital. New York: William Wood & Co., 1906.

THIS volume contains in small compass the main points in the diagnosis of the more common surgical affections. No attempt is made to go into fine points of detail, or to deal with rare conditions. The book is eminently practical, is well arranged, and should prove of value to fourth-year students in the hospital wards and in the dispensary.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-fourth Annual Meeting, Held at Toronto, August 21, 22, 23, 24, and 25, 1906.

(Special Report to the MEDICAL RECORD.)

(Continued from page 390.)

SECTION ON MEDICINE.

Third Day—Thursday, August 23.

Heart Block in Practice.—Dr. G. A. GIBSON of Edinburgh said that the recent interest in heart block had been one of the most helpful things for the study of cardiac disease ever secured. He had had one very characteristic case, in which the autopsy showed how thoroughly well grounded was the pathology of this little bundle of muscle fiber, so important for heart action. In this case the clinical symptoms had been typical, and after death the bundle of His was found paler than normal, even to the naked eye, though all other parts of the heart seemed perfectly healthy. This bank of muscle was seared with fibrous tissue and the striations of it were much less than normal. The jugular and radial pulses, when compared during life by means of careful tracings, had shown a complete divorce of the ventricle and auricle in action. Dr. Gibson demonstrated specimens from the case, showing the heart muscle fibers absolutely healthy within a millimeter of the bundle of His, though the bundle itself had many pathological changes. The vagus in cross section and in longitudinal section was perfectly healthy. In this case there was no history of specific infection, though some thickening on the anterior portion of the liver gave rise to the suspicion that possibly there had been an old syphilitic infection. Dr. Gibson said that the study of heart block and that the disturbance of heart rhythm from the standpoint of recent advances in knowledge were sure to be productive of most beneficial results.

Failure of Contractility.—Dr. W. S. MORROW of Montreal said that a number of cases thought to be heart block were really due to disturbances of the contractility of the heart muscles. These cases were very common, occurring much more frequently than had been thought. He demonstrated by means of a diagram how the ventricular systole might be delayed and how the conduction of the contractile impulse from the auricle upward and then downward might be delayed in various ways. He suggested that there had been a distinct misunderstanding as to certain phases of the heart action, and as a consequence a jumping to unjustified conclusions.

Case of Stokes-Adams Syndrome.—Sir JAMES BARR of Liverpool, England, described a typical case of Stokes-Adams disease, with epileptic attacks and eventual death. The patient at first had an attack of unconsciousness on rising during the night, then he fell while hurrying for a train and hurt himself, being unconscious for some time. He continued to have such attacks. When first seen he had a pulse of 17. He never had a pulse higher than 24. He had frequent attacks of unconsciousness, during which his pulse became very slow and his face very pale. Recovery from his attacks was always ushered in by a flushing of the face. During short epileptic seizures the face and arm were specially affected. During these attacks, for thirty seconds there would sometimes be no pulse, then for some minutes there would be a beat every five seconds. Then there would be another intermission of ten seconds, and then a gradual acceleration of the pulse rate until the pulse was beating 17 per minute. The general condition was not such as to suggest the serious lesion at work. Both ventricles were enlarged, the left the most, and it was judged before death that the heart weighed about twenty ounces, and at autopsy it was found to weigh nineteen and one-half. The patient frequently helped himself, stretching out his hand to take a glass of water, and in the interval of his attack was perfectly conscious. His arteries were thickened, but not much beyond his years—he was sixty-six—and were somewhat tortuous. No beating could be felt in their walls. A curious effect was the stimulation produced by deep breathing. During deep breaths, when the patient held the air in his lungs, two or three muffled beats could be heard in between the regular contractions. The coronary arteries were thickened, especially near the bundle of His, and there was a great deal of connective tissue within the bundle. The speaker could not persuade himself that the bundle of His was so important in this matter as had been taught. He did not think that it conducted impulses, and there was no evidence of its contraction. It must not be forgotten that the heart was really two organs of different functions; one pumped blood through the lungs, the other through the general circulation. They were connected together only for nutritional and economical reasons. The tendency of the right auricle to contract of itself must not be forgotten. Dr. Barr had often seen it continue to contract even on slight stimuli several hours after death from asphyxiation. This was true in human beings, and it was evident that this portion of the heart was the most excitable. The right ventricle was more excitable than the left. When the blood from the general circulation got into the right auricle stimulation at once resulted and the heart contracted. Further studies on these subjects were absolutely necessary before conclusions could be drawn.

Fourth Day—Friday, August 24.

Diet in Typhoid Fever.—Dr. F. T. SMITH of London said that the worst feature of the present almost universally accepted treatment of typhoid fever lay in the fact that patients were not given enough to eat. He insisted that when a typhoid fever patient was hungry he should be fed the things that he cared for, without much regard to any arbitrary rule. The patient was not a case, but an individual, and the diet suitable to the patient must be selected without any reference to his temperature. An exclusive milk diet had not availed to save patients from the worst complications, and perforation and hemorrhage occurred in spite of the greatest care in this matter. Only certain kinds of food must be absolutely excluded. Among these were nuts, grapes, oranges, strawberries, gooseberries, and figs, because they contained small indigestible pits which were irritating to the typhoid ulcers. If patients craved these, they might be given after having been strained through muslin. Only two things served as indications for the diet. Nothing must be given that caused nausea or distention. These could be kept fairly under control, by feeding not by routine, but according to the indications in each case. When Sir William Gull allowed the King almost on his deathbed from typhoid fever to take a glass of beer, that ought to have settled the enthusiasm for exclusive diet, but the cry was still milk, milk, milk, until now Dr. Smith had more sympathy with the patient than with the old fogy notions that dictated such an exclusive diet. The most important thing was to treat the patient as an individual. In ten years Dr. Smith had had under his care 113 cases of typhoid fever, with 24 deaths. Only four of the deaths occurred after solid food had been taken, and the remainder were of patients who were in very serious condition when admitted to the hospital and were given only water and at most an exclusively liquid diet. In over one hundred cases there had been only 2 per cent. of complications. One patient suffered from thrombosis, one from abscess, and one from periostitis. In the records of over one thousand cases in the same hospital, treated by an exclusively milk diet, there were over 10 per cent. of complications. The absence of complications, Dr. Smith said, was an extremely important matter. The average stay of his patients in the hospital had been forty-eight days. The average stay of patients in the wards of his colleagues had been fifty-seven days. The average day of the disease on which patients were dis-

missed from his service was the sixtieth. The average stay in the other services was till the seventieth day of the disease. This represented a clear saving of ten days, an extremely important consideration for workingmen, and besides, the absence of complications made recovery more complete and subsequent morbidity much less. Dr. Smith pleaded then for giving up the eternal milk diet, which was founded only on the prejudice of old-time physicians who had been afraid of doing injury and did not realize that this starvation diet was of itself an extreme factor in producing death from typhoid fever.

Dr. McCallum of Toronto said that he had recently been asked a medicolegal question as to what constituted solid diet. He found it extremely hard to decide. Practically all food that was taken became liquid in the stomach. His answer was that meat must be considered a solid diet, yet even this was doubtful. There had been much prejudice in this matter and there was room for distinct advance in our knowledge of what constituted a solid diet.

Dr. J. Hutchison of London said that he agreed with Dr. Smith that there was too much fear of doing harm by adding to the patient's diet in typhoid fever. Mechanical irritation of the ulcers was not likely to take place. The danger of the mixed diet was rather that it might produce distention or indigestion. Milk, by producing lactic acid, served to prevent fermentation, since most bacilli did not grow in the presence of lactic acid. This was its main advantage. The individual appetite must be consulted, and it seemed probable that if the patient really desired a particular kind of food, then the possibility of digesting it was also present. Russian investigations into digestion had shown the value of this question of appetite, and the indications should not be neglected. Meat could not be considered a solid diet, in his opinion, at least as regards the ileum, since surely it would be dissolved before reaching this portion of the intestines. Prejudice rather than science had ruled in the matter of diet for typhoid fever patients, and it was time that a rational diet should be given.

Dr. Norman Walker of Niagara Falls, Ont., said that he had found fruit juices very valuable as an addition to the diet of typhoid fever, especially during the first week, when the tongue was coated and there was no desire for food. These sweetened the stomach and proved very grateful and cooling to the patients. He had found grape juice especially valuable, and recommended it to those who were looking for something for their patients at this stage of the disease.

Dr. McCaskey of Fort Wayne, Ind., said that there was a larger percentage of residue from milk than from almost any other form of food. It was often thought to be completely absorbed, but any one who knew much about autopsy records realized what hard curds might be found in the intestines. Certainly a change to animal diet was a desirable improvement. In spite of the prejudices to the contrary, meat left much less residue than milk. It seemed important to remove the purin bodies from meat broths, because these added to the danger of intoxication in typhoid fever, since they provided a very favorable culture medium for microorganisms. Bouillon was used to grow microbes on, and yet all of this material might be removed by repeated boiling.

Sir Thomas Barlow said that everyone of large experience in typhoid fever knew how hard it was to withstand the pleading of the patients for something more than slop diet. This craving undoubtedly represented a physiological need and must be responded to as far as possible without danger to the patient. One sure result of a more liberal diet was earlier convalescence and less liability to complications that prolonged the course of the disease. If it were only that there was less likelihood of thrombosis, this was of itself sufficient to justify a liberal diet. Unfortunately if patients were kept on a very low diet they were apt to bolt food when given to them, and they craved it so much that visiting friends surely brought it to them, and the result was perforation and hemorrhage. The speaker said that Trousseau's method should be followed. Meat should be finely scraped and then boiling broth poured over it; this made a very grateful addition to the diet. Other things might be ground up with mortar and pestle. As a routine practice the use of fruit juices was not only grateful, but had distinct nutritive advantages. The coated tongue of patients often bothered physicians and their patients, but the first bit of food they had to chew removed the coated tongue. Some food to chew should be given regularly, for digestion was greatly helped by means of the salivary secretion, and unless there was chewing this did not find its way into the lower digestive tract. Dr. Barlow sometimes had given his patients meat to chew for a while, forbidding them to swallow it. This of course could be done only with patients who were absolutely to be trusted. In this way the nutritive portions of meat were ingested and the fiber spit out. He did not consider that milk was absolutely harmless. If given in large quantities, without dilution by barley water or arrowroot, enormous craggy masses remained in the intestines, and might very well produce hemorrhages by abrasion of the typhoid ulcers. This was especially the cause of the small hemorrhages that occurred during the fourth week. Sir Thomas had found that seeds were very dangerous, and therefore he was cautious about permitting fruit unless properly prepared; typhoid fever was not a disease to experiment with, and additions to the diet must be made with great caution. Meat should not be allowed more than one day in three until its effect upon the temperature was noted. The temperature was not to be made a fetish, yet if the food given disturbed it, it was dangerous. Variation in the diet was the most promising improvement in the present-day treatment of typhoid fever that medicine now held out to us.

Dr. Smith, in closing the discussion, said in answer to a question, that whenever constipation occurred, that is, whenever a typhoid fever patient did not have a stool for twenty-four hours, the nurse had orders to give dram doses of sulphate of sodium every hour until a movement took place. He preferred that patients should have slightly constipated bowels rather than diarrhea. The most fruitful source of fatal diarrhea was milk given every two hours, whether patients wanted it or not. When patients did not want anything to eat it should not be forced upon them. To give food uncalled for was sure to produce nausea or tympanites. Dr. Smith knew no solid food that remained solid in the digestive tract except the pits of fruit, grape-skins, and the like, which were really not food. He considered it a mistake ever to let a typhoid fever patient get ravenously hungry. On the other hand, they must never be tempted to eat.' He had never regretted giving a typhoid fever patient only water, though he had regretted at times additions to the diet. He used chlorine water constantly in his wards because of its possible antiseptic effect, but he did not think that any form of treatment had much effect upon the disease. The most important element of any treatment was to treat the typhoid patient and not the typhoid fever.

Syringomyelia with Immense Cavity.—Dr. W. G. Spiller of Philadelphia, Pa., described a case of this disease with autopsy, in which the cavity was found to begin in the lower sacral region and extended all the way up through the spinal cord and the medulla and the pons, almost to the ventricle. This was considered to be only a well-marked case of the disease, and there was no suspicion before the autopsy of the extent of the cavity. The affection began when the patient was seventeen years old, and continued for nearly twenty years. There had been the usual symptoms, with dissociation of sensibility, with paralysis of the abducens nerve, and marked atrophy of one-half the tongue. There had been no further involvement of the cranial nerves. According to the literature of

syringomyelia, such an extensive cavity had been deemed impossible. Schlesinger had positively declared that it was impossible for the cavity to extend beyond the pons. It might involve the caudal portion of the pons, but no more. If there were other symptoms pointing to higher involvement, these must be considered as due to complications. It had been thought that a cavity in the medulla and the pons would be fatal before it would work much havoc in these all-important organs. These opinions were now seen to be wrong.

Sir THOMAS BARLOW said that this was an extremely instructive and interestingly exceptional case. He had never deemed it possible that a cavity should extend so high.

Dr. CAMPBELL MEYERS of Toronto said that Dr. Spiller's case represented a distinct advance in neurology.

Dr. Spiller, in closing the discussion, in answer to a question said that the sensation of pain, according to his idea, passed through the lateral columns of the cord through the tract of Gowers. He had found when lesions of these tracts were present that pain sensation had been lost, even though the feeling of touch was not impaired. He had observed that even the presence of miliary tubercles in the tracts of Gowers produced loss of pain sensation.

Philosophy and Psychasthenia.—Dr. J. J. PUTNAM of Boston said that the mental therapy of nervous and mental diseases was growing in favor, but that it was not yet enough studied. The popularity of Prof. Dubois' book, which showed how much could be accomplished, undoubtedly would prove very helpful in spreading precious knowledge in this matter. Philosophy and religion were two important factors for the treatment of these patients. There had been too much expression of disease in terms of physiology and chemistry. The spiritual side of man must be more recognized. Conscious states were the only true realities in existence, and must be recognized as such. Physicians must take up the study of philosophy as well as of natural science, if they would succeed with this class of patients. Ostwald's expression of consciousness in terms of physics, and Loeb's attempt in the same direction, were unfortunate steps backward.

Serum Treatment of Cerebrospinal Meningitis.—Dr. SIMON FLEXNER of New York said that there had been 4,000 cases of epidemic cerebrospinal meningitis in that city during the past two years, with a mortality of 75 per cent. A commission had been appointed to investigate its cause, and as a member of the commission he had come to certain conclusions. The affection was undoubtedly due to the diplococcus of Weichselbaum. This organism did not have a high pathogenicity, though when cultivated, if the microorganism was allowed to give up its toxins to a liquid, a rather virulent poison was obtained. To the microbe and its toxin the monkey was found to be very susceptible, and so a series of experiments were made in order to determine the possible efficiency of a serum for the disease. The monkey had very characteristic symptoms, such as retraction of the head, nystagmus, and a comatose condition, and other manifestations similar to those in human beings. The localization of the lesions was the same as in man. There was no haphazard distribution of the pathological changes; these were found on the posterior part of the cord and at the base of the skull. It was easy to produce the disease in an acute form in monkeys, but the chronic form was also found possible of induction after some experiment. It was found that the simultaneous injection of the serum and of the culture of the microbe produced no effect. If the serum were injected into the spinal cord even six hours after the diplococcus, the animal did not perish. Examination of the cord showed the microorganisms either dissolved or swallowed by phagocytes. It was found also that if large doses of the serum were given subcutaneously a beneficial effect was also secured. Not every case, however, responded to this form of treatment. Guinea pigs were protected as well as monkeys, but the observations on monkeys seemed most conclusive because of their nearer relationship to man. The question of preparing this serum in large quantities for man required that first it should be determined that horse serum, which was the only one that could be obtained in large quantities, was not detrimental to the cells of the spinal cord. Injections elsewhere had not proved so effective, and it was hoped that serum might be prepared for the direct treatment of the cord. In Germany there had also been an epidemic of the disease, and horses had been treated so as to produce the serum, which had been injected into the spinal canal, apparently without production of any serious harm. The full account of its efficiency had not yet been made up.

Mortality of Cerebrospinal Meningitis.—Dr. STEVENS of Glasgow said that twenty years ago there had been a slight epidemic of this disease in Scotland; twenty years before that it had been declared that the disease was so rare that it might be passed over in the text-books. During the present year, however, there had been an epidemic of nearly one hundred cases in Glasgow, with a mortality of about 75 per cent., and in about one-half of the cases the diplococcus of Weichselbaum had been found. No treatment seemed to do any good. He welcomed the discovery of a serum, then, and hoped that Prof. Flexnor's very judicial consideration of the subject would lead to the hoped-for results.

Dr. MCFARLAND of Albany, N. Y., said that Wessenhoffer, who had been appointed to investigate the epidemic of the disease which occurred in Germany, had decided that the germ usually entered through the pharynx. In treating the disease by injections into the spinal cord, one difficulty was to get sufficient fluid into the spinal canal to have an effect on the brain. There was a constriction of the canal just before it entered the brain which prevented any remedy from entering the skull in sufficient amount. The best treatment so far suggested was that of Lenhartz, who removed the fluid from the spinal canal in order to get rid of the toxins and bacteria.

Paracentesis of the Pericardium.—Dr. DOCK of Ann Arbor said that the fear of injury and the difficulty of diagnosis had kept pericarditis from being treated as scientifically as it should be. The diagnosis was easy in dry cases, or when from the nature of the disease pericarditis was anticipated and looked for carefully. It was always best if the heart action was interfered with to remove the fluid. There was some danger from wounding the heart, but in most cases such wounds seemed actually to stimulate. If nothing more would be permitted, at least puncture by an aspirating needle should be employed. A long needle should be used and inserted slowly. The lower the puncture was made the better. If there was dullness below the apex, then puncture should be made in the sixth interspace. The costoxiphoid space was an excellent place for puncture, and if this was negative the patient should be made to change position. As a rule, if the symptoms were serious, thorough evacuation of the pericardium should be secured. This required an operation, but it might be done under local anesthesia.

Gastric Neurasthenia.—Dr. HUGH A. MCCALLUM of London, Ont., said that there might be neurasthenia of every organ in the abdomen. Gastric neurasthenia there was, but also liver neurasthenia, kidney neurasthenia, and neurasthenia of other organs. The most prominent symptom of gastric neurasthenia was that the condition was worse when the stomach was empty. If the digestive symptoms were relieved by the bromides, then the condition was almost surely neurasthenic. If the dyspepsia was accompanied by much mental irritability, then it was almost surely neurotic. Every long-continued indigestion, presenting no vomiting of blood and no tumor, must be suspected to be gastric neurasthenia. The treatment consists in training the mind and the body. The mind must be kept off the

symptoms and exercise out of doors must be insisted on.

Dr. Putnam of Boston said that a typical stigma of gastric neurasthenia was the cardiopulmonary murmur. It occurred frequently in these cases and rarely in any others.

Dr. McPhedran of Toronto said that visceral ptosis not infrequently was at the bottom of serious, long-continued symptoms of indigestion, and must be carefully differentiated from the neurotic condition. As a rule, if the motility of stomach were maintained, then the patient was not seriously ill. No matter how much the organs might drop, if function continued all was well.

Dr. James J. Walsh of New York said that the term employed by Dr. McCallum seemed inadvisable. First, the set of symptoms called indigestion did not proceed entirely from the stomach, but from the whole digestive tract, and so should not be limited by the adjective gastric. As a matter of fact patients could get on very well without any gastric digestion if the stomach only moved the food on. Neurasthenia was only a long Greek word for nervous weakness, and as George Eliot said, we map out our ignorance in long Greek names. Patients hug the delusion that they have a special disease when they have only a set of nervous symptoms.

Dr. Calwell of Ontario said that not infrequently so-called nervous indigestion was associated with serious organic changes. Great care should be taken in such cases.

Preinsane Stage of Acute Mental Disease.—Dr. Campbell Meyers of Toronto pleaded for the recognition of the preinsane stage of insanity. Patients frequently exhibited diminished power of mental effort, lessened will power and memory, had changes of habits and of expression, were easily hurt, and became depressed long before the real mental disease developed. Treatment at this stage was most effective and so great care should be exercised in recognizing it. Slight symptoms must be looked for just as now they were in the preliminary stage of tuberculosis. In this way mental diseases would follow the lead of other branches of medical science.

SECTION ON OBSTETRICS.

Third Day—Thursday, August 23.

The Appendix Vermiformis in Relation to Pelvic Inflammation.—Dr. T. Arthur Helme of Manchester, England, read this paper, in which he condemned the indiscriminate removal of the appendix, when not the subject of disease, in laparotomies for pelvic disease, although admitting that in many women suffering from pelvic disease the appendix was found to be abnormal. He said it was quite common to find post-mortem evidence of appendicitis when no symptoms had been recognized during life, but it was important to remember that after a certain age very few organs in the body would pass an examination without being stamped as in a measure abnormal. He concluded that the association of appendicular and pelvic disease was due to contiguity rather than to continuity of structure, and that accidental positions of the appendix constituted an important factor in this association; that the appendix might be a frequent source of dysmenorrhea and mucocolitis; that the association of appendicitis and pelvic disease was the exception and not the rule; that the appendix was a highly differentiated structure, and played an important part in digestion; and that the routine removal of the organ when doing a laparotomy for pelvic disease was not justified.

Dr. D. Tod Gilliam of Columbus, Ohio, agreed with the essayist that there might be virulent disease of the pelvic organs without involvement of the appendix, and that the association occurred only by accidental contiguity.

Dr. A. L. Smith of Montreal believed that appendicitis and disease of the tubes were frequently coincident, though whether dependent one upon the other he was not quite certain. He thought that the same factor that predisposed to disease of the tubes predisposed to appendicitis also, namely, enormous increase in the number of colon bacilli.

Dr. Arnold Lea of Manchester, England, thought the profession owed a great debt of gratitude to the gynecologists who had been so indefatigable in removing the appendix, as Clark, Peterson, and Robb, who had shown that the appendix in these cases would not pass critical examination. He believed that in many cases of pain in the right iliac region in women attributed to the ovary, the trouble was really due to the appendix. He favored removing it in all cases where there was obscure pain in the right iliac region, otherwise in many cases a subsequent operation would have to be done.

Dr. J. H. Carstens of Detroit thought one could not lay down a law applicable to every case. There was, of course, increased danger in opening the intestinal tract, and the matter of time, too, was of importance. He believed that sufficient to the day was the evil thereof, and he always let the appendix alone unless there was evidence of disease. He did not, however, believe that the appendix had any physiological function.

Dr. J. A. Temple of Toronto said that Dr. Carstens had voiced his own feeling in the matter; he thought the indiscriminate removal of the appendix was unwarranted unless there was adhesion to the other organs, or inflammation.

Dr. Lockhart of Montreal thought that in the complication of appendicitis, with disease of the tubes, the appendix was not the offending organ, but became diseased secondarily. He did not believe its removal when the abdomen had been opened affected the prognosis at all, and he generally gave the patient the option of having it removed at the same time. He was not willing to believe that the appendix had anything to do with intestinal digestion.

Dr. Cuthbert Lockyer of London, Eng., spoke on the subject from the standpoint of the obstetrician, as he had had several cases of appendicitis complicating pregnancy. It had been questioned whether pregnancy did not predispose to appendicitis, though most authorities had believed that it did not. When it occurred as a complication of pregnancy it tended to a mild course, and was not fulminating because of the general hyperemia of the pelvis at such a time.

Dr. Holmes of Chatham, Ont., thought that pregnant women bore surgical operations very well, and he had removed the appendix from a woman four months pregnant in whom the abscess had ruptured into the peritoneal cavity. He believed the appendix should always be removed in doing a laparotomy upon a woman, because of the liability of trouble at the time of pregnancy.

Dr. Helme, in closing the discussion, said that he was gratified to know that his kinsmen on this side of the water were so in harmony with him in the matter. He deprecated, however, the practice of allowing the patient to decide whether or not the appendix should be removed at the operation. He believed in preserving any organ that might possibly be of use unless there was some definite disease.

Antistreptococcus Serum in Puerperal Septicemia.—Dr. Murdoch Cameron of Glasgow reported two cases of this affection, in both of which the serum had a very remarkable effect; the writer was convinced that without the serum treatment both patients would have died. He said he could also quote instances where it had failed, but there was no doubt in his mind that there were cases in which it was of great value.

The Gilliam Operation for Uterine Suspension.—Dr. D. Tod Gilliam of Columbus, Ohio, at the request of the President, described his method of operating, which he believed to be the simplest of all the operations devised for this purpose. An abdominal incision three or four inches in length was made in the median line, between the umbilicus and pubes, adhesions were broken up, and the fundus was brought forward. The broad ligament was picked up

with the finger and the round ligament then caught with the bullet forceps, a thread placed under it, and the ends brought out and secured to keep control of the ligament. The other ligament was sought for and secured in the same way. At a point one and a half inches from the pubes the peritoneum, muscle, and fascia were caught up with volsellum forceps and pinched together, the edges of the three layers being regular. The skin and superficial fat being drawn in the opposite direction with a sweep of the knife, the aponeurosis was laid bare and with the Cleveland ligature carrier; a stab wound was made about one inch from the edge of the abdominal incision; the jaws of the ligature carrier were brought into view and opened for the ligature; the thread on the round ligament was placed in the jaws of the carrier, which was then withdrawn, bringing with it the ligament. A catgut suture was then passed through it and back again, and tied.

Fourth Day—Friday, August 24.

Eclampsia.—Dr. Evans of Montreal read a paper on this subject, in which he recognized two forms of the disease, hepatic and renal, the former of which was the graver and gave less opportunity for general treatment. He believed that the degree of pulse tension was of greater importance from the standpoint of diagnosis and prognosis than anything else. Treatment must depend upon the type of the disease and the severity of symptoms, emptying of the uterus not being the sole or most urgent treatment. In the writer's opinion, chloral and chloroform were the sheet anchors in treatment, chloroform not to be used, however, during the convulsions. Opium or morphine, while it undoubtedly acted favorably on the nervous system, interfered with the processes of elimination and prolonged the coma. Veratrum viride relieved the tension, but at too great a cost, and should be very carefully used. Operative treatment depended upon condition of the os and viability of the child. Decapsulation might be employed in cases of anuria.

Dr. K. C. McIlwraith of Toronto was glad to hear so much stress laid upon the matter of pulse tension as a means of ascertaining the state of the patient. In the preeclamptic state the pulse tension was the best indicator of danger of convulsion. Subsequent to convulsion, the tension fell, and before a convulsion rose again. A feeble and low-tension pulse from the start was a symptom of great gravity. He referred to treatment with thyroid extract, as instituted by Nicholson of Edinburgh, and thought it of some service as increasing the flow of urine; he thought, however, that it tended to cause postpartum hemorrhage.

Dr. H. L. Reddy of Montreal believed eclampsia preventable as a general rule, when the patient was properly examined and cared for. In one case in which sudden blindness had occurred, he had done a lumbar puncture, removing about an ounce of fluid, with good results and recovery. It was his practice to empty the uterus as rapidly as possible, and he believed such treatment to be almost invariably successful. Had had no success with thyroid. He thought in case the os was hard and the cervix long a cesarean section was justifiable.

Dr. J. A. Temple of Toronto said that his experience with blood-letting in suitable cases had been most excellent. He used chloral, but had more faith in morphine, given in large doses hypodermically. When the os was hard and unyielding he would not resort to forcible delivery.

Influence of Lutean Secretion on Uterine Movements.—Dr. J. M. Kirkness of Edinburgh read this paper. Fresh extracts of the corpus luteum were used, and in the living subjects the material was injected into the external jugular vein. Cats, rats, and guinea pigs were used. It was also tried in strips of uterine muscle. In all cases rhythmic contractions were produced. The tracings of the movements were diagrammatically illustrated by a series of charts. Nuclear proteids from the ovary and other organs were used as controls. With strips of uterus and with the uterus *in situ* the same results were obtained. Alcoholic and ethereal extracts did not act as well as the aqueous extracts.

Ectopic Gestation.—Dr. J. F. W. Ross of Toronto read this paper. The writer drew his conclusions from a study of many cases. In 1,500 laparotomies, 70 had been done for ectopic gestation. The mortality was 8.4 per cent., with no deaths in the last 36 cases. In five the operation was performed twice. In one case there was coincident intrauterine and extrauterine gestation. Average age, thirty-two. In 74, or over 75 per cent. of cases, there was amenorrhea. In 10, irregular menstruation. In only 5 was discharge of decidual membrane noted. There was history of one or two missed periods, colicky pains, some discharge of blood, and slight enlargement of uterus. In 90 per cent. of the cases there was sudden severe pain, with rupture of tube, there was a dark, bloody vaginal discharge, and partial or complete collapse. The conjunctiva showed the profound anemia earlier than did the lips. In 80 per cent. of the cases an irregular mass was discovered to one side and behind the uterus. In operating, the abdominal route was followed in all cases. Many of those operated upon had subsequent normal pregnancies. Treatment by operation was undoubtedly the safest, and should be performed as soon as the diagnosis was made; if this was properly done by a skilled operator the mortality was very low. He made it a rule to remove the blood clots thoroughly from the cavity; even patients who were pulseless on the table were washed out as thoroughly as those who had not collapsed. He believed the ovary should not be removed if in a healthy condition, nor should the other tube. Drainage should not be employed unless necessary, but no débris should be left behind.

Dr. Murdoch Cameron of Glasgow read a paper on this subject, dealing with it from a practical point of view. He thought that accuracy of diagnosis in experienced hands was now such that delay in operating was not to be considered. In most cases early signs of pregnancy were present, and a mass could be made out on one side of the uterus. The pain of rupture was generally followed by collapse. It was of first importance that the condition be recognized early. Where there was history of irregular menstruation with signs of pregnancy, the condition was to be suspected. When rupture occurred the symptoms were so alarming as not to be mistaken. He advocated drainage with a glass tube after removal of clots. He preferred the abdominal route rather than the vaginal. He exhibited photographs of twin tubal pregnancy, with decidual cells in the other tube.

Dr. Dorsett of St. Louis had operated in fifty-four cases, and in the last case the usual symptoms were not present, but the cul-de-sac of Douglas was found bulging at the introitus. There was no sudden pain or discharge. He expressed a preference for the abdominal operation, as one could not tell just where the placenta might be located and attached.

Dr. Giles of London, Eng., did not agree with previous speakers that the diagnosis was a simple matter; sometimes one ran across a case entirely by accident. One patient had consulted him to know if there was any reason why she should not become pregnant; on examining her he found a slight swelling on the left side, and as she had missed one or two periods he suspected extrauterine pregnancy, which proved to be correct. Another patient had been under treatment for gastric ulcer and perforation of the ulcer had been diagnosed, when a tubal pregnancy ruptured. He regarded every case of extrauterine pregnancy as one of malignant tumor, to be operated upon at once.

Dr. John Edgar of Glasgow would not advise removal of the other tube, as patients often became subsequently preg-

nant in the normal way. He believed there was a class of cases in which the vaginal operation was of advantage; those in which there was a so-called hematocele, with bulging down of the vaginal vault.

Dr. Louis S. McMurtry of Louisville believed there was now perfect agreement among surgeons of all countries that instant operation was necessary.

Dr. F. A. L. Lockhart of Montreal said that amenorrhea was not necessarily a symptom. He had had forty cases, and was quite positive that a large minority of them did not have that symptom. In a certain percentage of the cases diagnosis had been made by the irregularity of menstruation and the appearance of an increasing mass in one fornix. He preferred abdominal section, seeing no reason for opening the vagina and groping around in the dark. He would not remove the other tube.

Dr. F. S. Webster of Toronto did not think there should be any trouble in the diagnosis of tubal pregnancy. In his experience, however, the symptom of amenorrhea had not been the rule; there was irregular menstruation. He thought the interference with menstruation depended upon the location; if the ovum was near the fimbriated extremity menstruation was not likely to be interfered with. He deprecated the custom of surgeons speaking of vaginal operating as groping in the dark; one could see in this operation perfectly well what was being done, and he thought that in many instances it was the preferable route. He believed that 99 per cent. of pelvic diseases could be handled through the vagina.

SECTION ON SURGERY.

Fourth Day—Friday, August 24, 1906.

Perineal Stop for Retaining the Catheter After External Urethrotomy.—Mr. C. Hamilton Whiteford of Plymouth showed this instrument, which he had devised, for keeping a rubber catheter in the bladder after external urethrotomies.

Surgical Relations of the Parathyroid Gland.—Dr. W. G. MacCallum of Baltimore said that it was well known that the parathyroid gland was very important in connection with the untoward results following operative interference upon the thyroid gland. Also that parathyroid gland had a close connection with tetany of gastric origin, a point that had been particularly observed by medical men. But in the hands of many surgeons the precise relationship of this gland with the surrounding tissues seemed very uncertain. Although the effects of extirpation of the gland was clear enough, it was very important to elucidate the nature and relationship of the thyroid gland. When surgeons removed the entire gland they were surprised to find the appearance of severe phenomena of a convulsive nature. It was only after observations upon the parathyroid gland that attention could be directed to its relation to tetany. It had been clearly proven that tetany, and convulsive features, and acute reactions after the complete removal of the thyroid, were due, not to the removal of the thyroid alone, but to the removal of the parathyroids. It was at once recognized that it was dangerous to remove the whole thyroid gland; so they limited themselves to the removal of a portion only. Dogs, cats, monkeys, and other animals had been experimented with; after complete removal of the thyroid, convulsive movements of the muscles of the body became most marked. Some looked upon tetany as some form of autointoxication, and this conception was supported by the fact that one might bleed an animal in tetany and infuse saline solution into the veins, and cure this tetany for a short time, probably one or two days. But if one strove to produce tetany by using the blood of an animal the subject of tetany, the results would be disappointing. As to the nature and origin of the toxic substance, not much was known. Stagnation of material in the stomach seemed to be one cause of tetany. One man had been observed in the hospital with symptoms of tetany, having attacks lasting one or two days, and he had an enormously dilated stomach. While in the hospital he ate quantities of food; this was followed by the most violent attacks of tetany and death. His death was probably due to absorption of poisonous material from the stagnated substances in the stomach. In all probability the parathyroid secretion given out normally was not sufficient to neutralize all the toxins in the man's stomach. Whatever the source of the poison, it affected the central nervous system. This poison was somewhat analogous to the tetanus toxin in this respect. Dr. MacCallum then considered the mode of action of the parathyroids, in neutralizing the poison, as well as parathyroid extract in experimental tetany. The most fatal form of tetany was produced in dogs, and when they were apparently moribund they were given parathyroid extract, which was followed by recovery. It was found possible to repeat this two or three times, using an emulsion of ox parathyroid, recovery being prompt and lasting for a long time. The conclusions reached were that life could be maintained if large quantities of parathyroid material were used. He reported the case of a woman who had one-half an enlarged thyroid removed because this mass compressed the trachea. Some years later the other half became enlarged, and something had to be done in order to save her life. Operation was done, avoiding injury to the parathyroid. Yet when a piece of the removed material was examined microscopically, parathyroid gland was found. After a day or two she began to show signs of thyroid insufficiency, a feeling of distress in the thorax, arms, and legs, but without any convulsive seizures. The administration of parathyroid gland from the ox gave her complete relief, and at once. If this treatment was stopped, even for a short time, the symptoms reappeared. She was still taking the parathyroid material and was enjoying good health, taking three or four glands a day. The parathyroid gland of an ox was easily obtained from the slaughter-house. In studying the topography of the parathyroid glands, sixty-five or seventy cadavers were used, and it was noted that the glands lay in loose areolar tissue, in which there was much fat, and the number of glands found was in direct proportion to the persistency with which they were searched for. One of the most characteristic features about them was their consistency. They were of a yellowish fawn color, contained many blood-vessels, which could be seen running over their surface, which was smooth and glistening. Four glands were usually regarded as the proper number, two in apposition with each lobe of the thyroid. In nine cases of exophthalmic goiter the parathyroids were carefully examined and found to be perfectly normal, and, therefore, there was nothing, in his opinion, to support the theory that the parathyroids had anything to do with the development of this disease.

Sir Victor Horsley of London said the observation just made by Dr. MacCallum regarding exophthalmic goiter was of fundamental importance. This disease was not in any sense a perversion of physiological activity of the parathyroids; it was, on the contrary, a perversion of the normal secretion of the thyroid gland. Sir Victor said he had been struck for months in removing goiters that there was a distinct class of neoplasms exactly resembling thyroid tissue. He agreed with Dr. MacCallum that when they extirpated what appeared to be isolated goiter it was their duty to be very careful in the inspection of its site; if they found that this isolated tumor was in the neighborhood of the hilum of the gland and along its posterior border, it was not at all improbable that they would find the tumor resembling the parathyroid gland. These tumors, he believed, should be extirpated, but with exceeding care. Often they ran a course of a very malignant character.

(To be concluded.)

AMERICAN ACADEMY OF MEDICINE.

Thirty-first Annual Meeting, Held in Boston on June 2 and 4, 1906.

THE PRESIDENT, DR. DONLY C. HAWLEY OF BURLINGTON, VT., IN THE CHAIR.

Maturation and Senility.—Dr. A. L. BENEDICT of Buffalo referred to the different rates of maturation and senescense in animals and human beings, and spoke also of cretinism and geromorphism. The variation of death rate and longevity for the sexes received full consideration. Other factors considered were physical definition of senility; diseases characteristic of extremes of life; essential identity of apparently widely different diseases, as apoplexy and diabetes; difference of diseases called by the same name, when occurring at early and late age. Inquiry was made whether old age was a cause of death; whether senility was distinct from the sum of cumulative pathological processes accidentally, but practically inevitably encountered; whether a given degree of physical senility, as ordinarily estimated, by years, was characterized by a corresponding degree of histological degeneration. Capacity for mental work in relation to maturity and senility was considered, and inquiry was made whether or not it depended on previous intellectual acquisition or exhaustion, or upon essentially physical conditions of the brain.

Dr. J. W. GROSVENOR asked the author of the paper to give a definition of the term "senility." Personally he had been unable to find a good definition of the word.

Dr. J. T. SEARCY thought the natural processes of senility were illustrated in the process of the mental development of the person from childhood to old age. The senescense of a man, he thought, began with his acquiring ability; how soon it set in, and how soon the stage of senescence called dotage began, and how it differed in individual persons, were regarded as interesting questions. Some men of fifty were as far advanced in the failure of mental ability as other men at eighty.

Dr. CASEY A. WOOD of Chicago remarked that one of the processes seen with advancing age was the change in the smaller vessels, and only in the fundus of the eye could this be actually demonstrated. Some of the organic changes in the eye took place at the twenty-fifth year of age. In almost all persons past the fiftieth year these changes were present.

Dr. LEARTUS CONNOR spoke of the difficulty of differentiating the natural changes in the eye due to advancing age and processes of disease.

Dr. WOODS HUTCHINSON of Redlands, Cal., thought the tendency of the Anglo-Saxon race was to cling to life, rather than to use every endeavor to make the most of it, being willing for old age to come as rapidly as it would.

Dr. A. H. TUTTLE spoke of his studies of the life history of small sea animals, in his observation of the development of the eggs in the sea water and under artificial means. According to change in environment there was marked change in the development of the animals and the production of monstrosities of all kinds. These changes he felt had a certain significance in connection with the development of malignant disease, and especially of cancer. The changes of senility also he felt had a certain bearing upon the subject.

Dr. JAMES A. SPALDING of Portland, Me., related an instance in which there was a difference of fifty-eight years and ten months between the age of the first child of a given father and the last. He thought the study of the eye in old age offered a clew to the other conditions going on in the human frame, and therefore of interest in the study of senility. When one ceased to be useful and his friends had all gone before, he thought it scarcely worth while to study to prolong life.

Dr. WOODS HUTCHINSON thought the work of the profession was to make life more vigorous during its existence, rather than to make it last longer. He would drive the machine as fast as possible while it lasted, and then to the scrap heap.

Dr. FREDERIC H. GERRISH of Portland, Me., thought that for every one old age was ever a receding point. In his early teaching career he had determined that when he reached the age of sixty, if then teaching, he would resign, believing that schools were injured by retaining in the faculty men who had passed their prime. He thought it of immense practical value that young men likely to hold teaching positions should recognize the fact that they were not good judges of their own capacities when they got into the fifties and sixties.

Dr. WILLIAM R. WHITE of Providence, R. I., thought Dr. Hutchinson's theory would not work out satisfactorily in practice. The machines, instead of going readily to the scrap heap, were converted into neurasthenics, hemiplegics, and other variously affected persons filling the asylums and institutions.

Manual Training for Medical Students and Instruction in the Principles of Psychotheraphy.—Dr. GERSHOM H. HILL of Des Moines, Ia., in this paper referred to the present-day tendency in business and education toward civilization. While believing that medical education should be technical, he also believed that it should be well balanced and as general as ever before. Some livelihoods to-day were gained with brains rather than with muscle, and life was indoors and sedentary, neurotic conditions, nervous diseases, and psychopathic ailments were very frequent. While drugs and surgical operations could cure many diseases, there were many patients suffering from impaired physical or mental ability whose condition was said to be functional. Here it had been demonstrated that great benefit had been secured from baths, massage, osteopathic manipulation, and the application of electricity. Therefore it was his opinion that medical students and internes should be taught more completely how to apply these methods, in order that they might instruct nurses and patients. Such instruction was regarded as important as that for the application of a bandage. Neurasthenia, hypochondria, hysteria, and melancholia in addition to other methods of treatment required psychotherapeutic management. These conditions were regarded as common and mixed, and demanded careful investigation. To treat successfully, the physician must get the confidence and the control of such patients, consequently it would seem worth while for the medical college to give more attention to the principles and the art of psychotherapy.

The Friendship of Drs. Nathan Smith and Lyman Spalding.—Dr. JAMES A. SPALDING of Portland, Me., stated that everybody acquainted with medical history had heard of Dr. Nathan Smith, the founder of three medical schools. Few knew anything about Dr. Lyman Spalding, colaborer with Smith at Dartmouth Medical School, pioneer in smallpox vaccination tests in the United States, lecturer in Fairfield Medical School, and the originator of the U. S. Pharmacopœia. This paper, by a grandson of Dr. Lyman Spalding, drew a brief sketch of his life, showed the influence exercised upon his early career by the presence in the same town (Cornish, N. H.) of Dr. Smith, and closed with the reading of unpublished letters from Dr. Smith, exhibiting close business, medical, and social friendship between the two men during the term of their mutual lives. The letters quoted from were recently discovered and embraced the period between 1796 and 1819.

Heredity and Environment as Causes of Delinquency and Crime.—Dr. DONLY C. HAWLEY of Burlington, Vt., in his Presidential Address with this title, stated that while scientists admitted the heredity of physical and psychological peculiarities, the weight of their testimony was to the effect that this phenomenon, while frequent, was not constant. The influences especially opposed to heredity were given as: (1) Education; (2) the instinct of initiation; (3)

the innovative force of individual initiative. In studying heredity a prominent place must be given to the inheritance of acquired characters, which were constantly changing through the modifying influences of environment. While a thorough knowledge of the biological law of heredity was of vital importance there was need for a wider recognition of the tendency of Nature to "throw back" to the normal or average. This principle of reversion, it was said, had been called "the most cheering fact met with in the study of heredity." Disease was stated to be not so much an inheritance as a tendency to disease. The tendency of the delinquent and the criminal, so far as inheritance was concerned, was to repeat the sins of the fathers under like unhealthful and perverse conditions. Criminals might in some instances inherit direct tendencies to crime. The views of such extremists as Lombroso were questioned, and especially in regard to the criminal classes should not be accepted without challenge until better evidence could be adduced to show that the defects were a positive inheritance rather than a resultant of defective development, due to bad environing circumstances, drunkenness, etc. To prevent habitual crime there must be the saving of the young offender from the acquisition of fixed habits of crime, largely the result of degenerate social conditions. Experience in the rescue of the young from conditions of delinquency and depravity seemed to point to the fact that heredity had been overestimated as a cause of these conditions, and that bad environment was oftenest the cause of abnormal physical, mental, and moral growth. Future effort in the prevention of delinquency and criminology should be directed to the proper culture of the child. To let no child grow up a criminal should be the aim of the State, the school, the Church, and every good citizen. While the full accomplishment of this end might not be realized, the belief was entertained that factors in the production of delinquency and crime in the young might be greatly minimized.

How May the Medical and Teaching Professions Cooperate to Improve the Moral, Mental, and Physical Condition of the Young.—Dr. S. A. Knopf of New York City made the opening address in this symposium. (See page 401.)

The Duty of the Family Physician in Regard to the Proper Mental and Physical Development of the Children Under His Care.—Dr. Dudley A. Sargent of Harvard University in this paper referred to the lessened number of young men adopting medicine as a profession. To realize the highest ideal of medical science, not only was it necessary to know the origin and nature of disease, but to know intimately the man, woman, or child to be treated. In the knowledge of human nature it was asserted that the ignorant quack often surpassed the learned physician. The knowledge of the self-limitation of most diseases, provided the individual has sufficient resistance, was said to have placed new responsibilities upon the medical profession, and both the community and the physician should be educated to these new responsibilities. In the public schools he would have instituted the thorough physical examination of children at least once a year and subsequent daily inspection, which practice should be extended to factories and establishments employing many persons. The remarkable success of the Health Education League of Boston was mentioned as illustrative of the possibilities of such a movement. In the light of the present knowledge of the cause of moral, mental, and physical disease, the author believed that there was a much greater necessity for the physician to make periodical professional calls than for the pastor. Before the physician, however, could assume this function, the public must realize the value of preventive medicine and make its practice possible by an assured income to the physician. There should be common sense talks with prospective fathers and mothers; and persons anticipating marriage, and known to the physician to be mentally, physically, and temperamentally unfitted for each other, Dr. Sargent believed should be so informed in the proper manner. Instruction upon the arrival of the first infant was regarded as a duty of the physician, and this oversight should continue through the first seven or eight years of the child's development. The matter of school furniture deformities was considered. At the approach of puberty the children should be talked with by the physician concerning the mysteries of the generative functions, a natural approach to which subject was suggested to be through the nature studies of plants and animals. Up to the age of puberty he thought the mental and physical activities of the boy and girl should be the same; afterward, much of this activity should be essentially different. Concerning venereal diseases, he would have the family physician speak very plainly to both sexes.

The Sanitary Regulation of the Schoolroom with Reference to Vision.—Dr. Casey A. Wood of Chicago in this paper said that were the ocular apparatus of the average child by nature adapted to the amount and kind of work he was ordinarily called upon to do, the consideration of school hygiene would be unnecessary. In considering the illumination of the schoolroom, reference was made to the dictum of Risley, that at any hour of the day in any season of the year it should be possible to read the finest (diamond) print in any part of the schoolroom. He regretted that this dictum was often overlooked. Continual agitation of the importance of illumination in schoolrooms had led to the demand in Chicago for better built and better lighted schoolhouses. Where artificial light was found to be unavoidable, the light should resemble as nearly as possible diffuse sunlight, and should shine upon the work to be done rather than into the eyes of the pupil. While electric light was said to be preferable to gas or kerosene, it was also regarded as capable of greater harm to the vision, and much more likely to produce eyestrain unless judiciously arranged.

The Training of the Mentally and Morally Defective Child.—Dr. Maximilian P. E. Groszmann, who presented this paper, distinguished sharply between the lower grades of mental and moral defectiveness, such as would demand lifelong segregation, and that class of children whose defects were less grave in character, and who were, therefore, trainable. Attention was called to defects in the sense organs, nasal troubles, catarrhs, digestive disturbances, and adenoid vegetations as frequent sources of mental and moral derangement. A fundamental requirement in the training of defective children was stated to be a systematic physical regimen adjusted minutely to the individual case. Stress was laid upon the value of rhythmical movements. There should be careful observation of nutrition and diet, and such tonic treatment as was required. The secret of training the mentally and morally defective was said to consist merely in understanding the causes and conditions of the individual defects and trying to develop the child within his own limits, stimulating the weak powers for good and crowding out the lower impulses.

The Advantages or Disadvantages of Coeducation After the Age of Twelve Years.—Dr. G. Stanley Hall, President of Clark University, suggested the disadvantages of coeducation after the age of twelve; first, by the fact that it violated a custom so universal that it seemed to express a fundamental human instinct. In all ages of history and in all stages of civilization, with few exceptions, the dawn of puberty was marked by segregation of the sexes, especially for every purpose that could be called educational. While immemorial customs were not of themselves decisive, it was thought that this consensus of the race at the very least threw the burden of proof upon those who would defy it. In the second place, the arguments against coeducation from custom were reinforced by many more or less systematic observations of children themselves. It was shown that in the family the age of twelve found boys and girls more or less segregated. This was marked in the matter of their amusements, in their choice

of reading and of work. Reference was made to recent laboratory tests on children to ascertain sexual differences, by which it had been shown that sex distinctions pervaded every sense and function. One prominent result of the investigations was that in all the perceptive, passive afferent powers, girls on the whole were fully equal and often excelled boys, and even at twelve were nearer to their full maturity of intellect than boys. They were already well on in the subtle acumen of tact, taste, appreciation, and intuitive insight which made the pubescent girl forever appear to be such a prodigy to slower ripening man.

Dr. William T. Smith of Dartmouth College said that the most obvious advantage of coeducation was economy. This principle of economy controlled in the making of new schools and colleges in the West, which were almost wholly coeducational. Another advantage mentioned was that the boys, being in possession of the educational treasures and traditions of the past, the best could not be secured by the girls at present unless shared with them. Other arguments for and against coeducation were given concerning the physical health of the girls; the mental needs of the girls; the character development of both sexes. The danger to the health of the girls in coeducation the author concluded was greatly exaggerated. With proper care he believed that they more frequently improved in health. In the bearing of coeducation on the mental needs of girls, it was argued that the girls averaged better work in the regular college curricula than the boys. The disciplinary course which was good for boys he thought was equally adapted to the girls. Concerning coeducation in its effects on character development, it was said that women exerted a refining influence on men, and association with men in study gave steadiness and continuity to the work of the women Nature had ordained that with sex should go a separateness in daily activities. This obtained in business, in scientific, literary, and civic work, and in the industries. The exceptions to this separateness were said to be the family relations and those social activities whose impulse lay in sex consciousness. Daily competitive association of the sexes in college was regarded as not strictly "natural."

The Dangerous Influence of Overtaxing the Girl's Mind, Particularly at the Age of Puberty.—Dr. Augustus P. Clarke of Cambridge mentioned as a potential influence in the overtaxing of the girl's mind her great conscientiousness in the acquisition of knowledge. He advised against the forcing of girls of mediocre powers in work for which they have no special desire. The conventionalities of society might also react unfavorably. The offering of prizes was shown to be not without danger to the young girl. The hope was entertained that by the influences of better hygiene, the selection of plainer diet, by the help of gynecic medical science, the avoidance of unnecessary social demands, the dangerous influences encountered at the age of puberty might be counteracted.

Dr. L. Duncan Bulkley of New York, in presenting a paper on the same subject, stated that the human frame was but a machine, marvelous in its powers of self-sustaining and self-reproduction, and showed its liability to derangement. Through infancy and childhood had been well guarded, the age of puberty had not been seriously enough considered and guarded. From what was observed of the effect of mental and nervous strain on the digestive and menstrual functions at all times, he submitted that for physiological reasons it would be expected that oxertaxing the girl's mind at this time would naturally result in serious consequences. He showed that clinical experience abundantly confirmed this, stating that he had seen many girls, often with trivial skin affections, who on close study were found to be in a lamentable state of ill health, all dating from mental or nervous overstrain in schools or colleges. He believed that many with unusual powers of health, or with most careful regulation of the whole manner of life and with wise direction of the mental strain, could attain high educational conditions, but that far more suffered in their physical state and were permanently harmed than commonly supposed. He believed that a great responsibility rested upon family physicians and specialists who chanced to see these patients, in early recognizing and properly treating the departures from perfect health which continually occurred in girls being educated, and in giving repeated warnings regarding the many elements causing derangement to health. Of these he instanced study too soon before or after meals or before bedtime, insufficient or irregular hours of sleep, erroneous methods of eating and drinking, eating between meals, etc. He believed that about the time of menstruation there should be less mental and physical exercise and more rest.

Dr. Edward Cowles of Waverly said that much of the overtaxing was due to the failure of the home and school to cooperate. There was said to be a wide variation of medical views on the relation of disordered reproductive processes to mental disease. The solution of the problems he believed would be more certainly attained by keeping in mind the fact that the reproductive processes as a whole and in all their contributing parts were essentially physiological. A physiological process could not of itself be regarded as a cause of disease. Interference with such processes might result in symptoms called pathological. It was pointed out that one of the notable dangers arose when the young girl was ignorant of the menstrual disorders, therefore careful and timely instruction should be imparted concerning the menstrual function. In conclusion he emphasized the importance of the intelligent care of young girls, teaching them that there should be a healthy exercise of mind and body for the maintenance of good health, and warning against the dangers resulting from overtaxing the mind as well as the body.

Dr. G. Stanley Hall, President of Clark University, referred to the widespread increase of interest in matters of the relation between disease, sex, and procreation. He alluded to the formation of a sociological society, the main theme of which was to study the functions of family, church, and state, and to assist in endowing future generations with the maximum of that most precious wealth, heredity, on the principle of Huxley, who had said that one ounce of heredity is worth a ton of education and environment combined. Dr. Hall spoke of the appalling results of gonorrhea and syphilis, and of the great necessity of teaching these established truths to children. They should be talked to before puberty concerning these truths in a plain, direct, and personal manner. Heredity was suggested as a suitable beginning topic, showing that all that was good in the individual was due to generations passed, and that the future depended upon the restraints and the sentiment of honor among young men and young women.

Dr. George Van Ness Dearborn said that in Tufts Medical College he taught the process of reproduction in mixed classes and could say that there was absolutely no sign of embarrassment in discussing the most technical matters. He regarded it as false modesty and prudery not to give to the public the truths concerning gonorrhea and syphilis.

Dr. J. Madison Taylor spoke of the desirability of impressing upon school boards the necessity of teaching the fundamental principles of pure science. While appreciating the difficulties of bringing such a proposition before the average school board, he felt that it would be a helpful factor in the education of children.

Mr. Safford of Beverly thought it not alone the conservatism of school boards which hindered the teaching of sexual matters in the schools, but that of the community as well. He thought much might be done by the medical inspector, and suggested as desirable compulsory physical examination, including the condition of the sexual organs.

Dr. Helen C. Putnam referred in particular to the influence of the schools on health, and their teaching of the origin of life. Her personal experience among pupils was

that ill health among pupils was far less often due to school than to the home; far less due to mental overwork than to violation of known principles in dietetics, sleep, and exercise. Out of 1,000 records of girl students, only nine seemed to need reduction of mental work (acute illnesses not included). Education for women, so-called "higher education," along certain lines was never more needed in the world's history. It was only part of woman's mission to bear healthy children; equally important was it that they be well reared. Above all, woman needed more knowledge of household and public sanitation and of personal hygiene; knowledge of the physics, chemistry, and biology of daily living. In a few of the schools where so-called "Domestic Science" was taught, along with the discussion of diphtheria and other contagious diseases, syphilis and gonorrhea were mentioned, not discriminating between the morals of victims of any of the contagious diseases. Pupils were told how and why contagions were to be avoided. Reference was made to the teaching of reproduction in a few of the schools visited, showing that the origin of life could be wholesomely, intelligently, and most profitably taught in public schools by competent instructors. One method was as follows: The pupils were boys and girls from twelve to sixteen years old. The instructor was a biologist ready for a Ph.D. degree. First the multiplication of amebas and other unicellular animals was studied; next multicellular animals through invertebrates, tracing simply the evolution of reproductive organs parallel with the evolution of the digestive and circulatory systems. Then reproduction was traced through vertebrates, including mammals. The children followed the teaching in absolute simplicity and purity of thought. No evil was taught, but the truths of normal life. A talk on human sex relations based on Dr. Prince A. Morrow's "Social Diseases and Marriage," closed the year's work. There was no shock to conventionalities, because the instruction began simply and developed gradually according to the evolutionary method of Nature. Dr. Putnam at the end of the school year had realized as never before what plastic material little children were in the hands of teachers. Their development was so largely according to the guidance and example of adults that profound regret must be felt to find in so many cases personal responsibilities so indifferently discharged.

Officers.—The following election of officers was announced: *President,* Dr. Casey A. Wood of Chicago; *Vice-Presidents,* Drs. Wm. L. Estes of South Bethlehem, Pa.; James A. Spalding of Portland, Me.; Woods Hutchinson of Redlands, Cal., and Guy Hinsdale of Hot Springs, Va.; *Secretary,* Dr. Charles McIntire of Easton, Pa.; *Assistant Secretary,* Dr. Alex. R. Craig.

The committee to investigate the teaching of hygiene in public schools, appointed in 1903, presented the fourth section of its report—a report of present methods of teaching hygiene in departments of physical training and of medical inspection. Owing to the crowded program and at the request of the chairman, it was read only by title and will be published in the Bulletin of the Academy. The committee consists of Dr. Helen C. Putnam of Providence, Dr. Edward Jackson of Denver, Dr. George G. Groff of Lewisburg. It has published a compilation of the existing laws requiring the teaching of physiology and hygiene, Bulletin, April, 1904; a study of those forty-six laws and a study of seventy-three text-books (and revisions) written since 1882, Bulletin, June, 1905; and a report on the present teaching of hygiene in departments of "domestic science" and of "nature study," Bulletin, April, 1906.

Dr. F. Trendelenburg of Leipsic was elected an honorary member of the Academy.

The birth rate for St. George's-in-the-East, London, the headquarters of the alien invasion, is at the rate of 60.8 per 1,000. This is the highest birth rate ever recorded in England.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Regular Meeting, Held April 17, 1906.

Dr. William F. Campbell in the Chair.

How Can the Physician and Layman Accomplish Most in the Fight Against Tuberculosis?—Dr. S. A. Knopf of New York read this paper. He said that the antituberculosis movement did not promise any financial gain to physicians. On the part of the latter it was entirely unselfish. It had come to be recognized that the medical profession owed in this campaign certain distinct duties to the public at large. The first of these was concerned with making an early diagnosis of the disease. The earlier the diagnosis the greater were the chances of cure and the less the chances of infecting others. The other duties were concerned with the method of treating the disease. It was the business of the physician to teach the masses that tuberculosis is preeminently a curable and preventable disease. The speaker advocated a regular, periodic physical examination of every member of the family, in order that all incipient cases might be detected in time. It was the physician's duty to interest all classes in the crusade against the disease. The rich were to be interested in its social aspects, and were urged to divert some of their wealth in order to promote the treatment of the tuberculous poor. The duty of the physician was also to teach the laity that tuberculosis is a chronic, infectious, and curable disease. It could be disseminated in four ways: by inhalation, ingestion, inoculation, and drop infection. The prevention of inhalation tuberculosis required the simple law that no individual should expectorate except into a proper receptacle. The ordinary spittoon was too small; the ordinary spitter did not know how to hit it. The elevated spittoon, of which the speaker demonstrated a drawing, was far more practical. Having a cover, it was more cleanly than the ordinary cuspidor. What was to be advised for street use? The consumptive in public places and in street cars, who by obeying the law made use of spit cups which he carried, was apt to be treated like an outcast. It was the duty of the public, in the presence of the consumptive who was obeying the law, to treat him with the utmost consideration. Phthisiophobia was a disease that ought to be strenuously combated. One was to distinguish between public and private phthisiophobia. The former was the more reprehensible. An example of it was furnished by Brooklyn, when a court injunction was obtained restraining the Health Department from establishing a public tuberculosis dispensary. The least conspicuous and at the same time most effective receptacles for sputum for street use, were square pieces of muslin. Ingestion tuberculosis was to be avoided by proper cooking of various articles of food. Inoculation tuberculosis was next discussed. The porcelain spittoon, with its rough or cracked edges, was a potent means of the dissemination of this form of the disease, among those whose duty it was to clean the spittoons. If a servant was cut while performing this duty, a copious bleeding of the wound was sufficient to prevent the infection. Drop infection was the result of unguarded mouth and nose during the act of coughing and sneezing. There was no such thing as a dry cough. The public were to be convinced that hereditary consumption did not exist. Postnatal infection accounted for the existence of tuberculosis in children. Mothers suffering from consumption carried their infants at the breast and coughed over them and kissed them. The act of crawling on the floor also favored the infection of children. The school children were to help in the fight against tuberculosis. The speaker had already issued his alphabet for the instruction of school children in the prevention of tuberculosis. Next to the obligation of fathers and mothers in the instruction of the children came that of the teacher. After these came the preacher. The necessity for proper ventilation of churches and Sunday schools was dwelt upon. The teacher was to emphasize the importance of deep breathing. Out-

door recitations were urged. Every school was to have a school physician. It was important that every child should get enough time to sleep. Many a little one was driven out of bed too early in the morning. Swimming lessons were to be taught. All classes and occupations might help in the fight against tuberculosis. The owners of department stores and of factories could provide sanitary quarters, reasonable hours for meals, and proper opportunities for the resting of their employees. What were the duties with respect to the care of the tuberculous? The most important was the use of God's unstinted air twenty-four hours out of twenty-four. Next were the use of plenty of water, both inside and outside. All these were to be under the constant watchful eyes of conscientious physicians who would occasionally help along with a little medicine. There was no specific, no climate, no special medicines. The consumptive was never helped or cured by alcohol; on the other hand alcoholism was one of the most powerful predisposing causes of tuberculosis. More alcohol was sold in the form of patent medicines than over the bar. Jacobi calculated that $200,000,000 was realized annually from the sale of patent medicines. Many of these were popular remedies with consumptives. It was sad to see venerable clergymen lending their names in the advertisement of patent medicines. It was theirs to save souls, and to leave the saving of bodies to physicians. Consumption could be cured in every climate of the temperate zone. The speaker did not depreciate the value of climatic treatment of tuberculosis, but maintained that when cured at home the patient's chances of remaining cured were better. He deplored the improper use of the term "sanitarium." Sanatorium was more correct, corresponding to the German, "Heilanstalt." The need of a sanatorium in Brooklyn was badly felt. The consumptive required constant medical supervision, fresh air day and night (the fear of night air was a nightmare). When discovered early, and sent to a sanatorium, the chances of cure of an early case were 75 to 85 per cent. Such a patient on returning home became a teacher and reformer. The sanatorium had other advantages. Not only was it not a menace to the neighborhood, but it actually reduced the mortality from tuberculosis in its own environment. This was shown by statistics gathered from a sanatorium town in Germany, where the consumptive death rate had been diminished by one-third. By virtue of the incitement to cleanly habits in the tuberculous, the well-equipped sanatorium became a blessing. The tuberculosis dispensary was a necessity. Here the patient was properly instructed, and received his own medicine; suitable cases were selected for sanatorium treatment. Without a diet-kitchen such a dispensary was inadequate. Just as the sanatorium was advisable for early cases, so the hospital was essential for advanced cases. It was important to remove hopeless cases from the tenements. These various institutions were to be multiplied according to the amount of population. Even then the problem would have been solved only in a measure. As long as the dark, dreary tenements existed, so long would tuberculosis exist. These tenements and the similar sweat shops had to be first removed. An appeal had to be made to the community and to fellow-citizens. Philanthropists had to realize their responsibility. More important than libraries would be a provision for well-ventilated living apartments for the poor. It was sufficient to evoke the greatest sympathy for the laborer, to see him after a hard day's work, returning home to his dark den, to partake of a poorly cooked meal. He was little to be blamed indeed if he took to drink. The speaker emphasized the importance of beginning at the bottom in the crusade against tuberculosis.

Dr. Joseph H. Raymond of Brooklyn, Chairman of the Committee of the Bureau of Charities on the Prevention of Tuberculosis, discussed the paper. He said it was always a difficult task to discuss a paper prepared and presented by an expert. Until twelve months ago nothing had been done in Brooklyn to prevent the spread of tuberculosis except what had been accomplished by the Department of Health. This was not so effective because it was not supported by the medical profession. One year ago the subject had been brought to the attention of the Brooklyn Bureau of Charities, a voluntary organization supported by philanthropic individuals. One of the first things which this bureau started to do was to try to establish a tuberculosis clinic. One year ago there had been no dispensary in Brooklyn in which consumptives could be given the special care and instruction which were their due. Such patients were not as a rule welcomed in the general dispensary. Without the tuberculosis clinic the crusade against the disease had to lag. It had been suggested that the Health Department should employ a corps of physicians to visit the homes of consumptives. This was impracticable. The department then decided to establish a tuberculosis clinic. The anomalous spectacle was then prevented by the Supreme Court enjoining the Board of Health from establishing a special tuberculosis clinic on the ground of danger to the public health. The department had already fitted up a house when it was enjoined by an injunction. This was afterwards made permanent. In order to solve the question that had been raised in this litigation, namely, whether there was any danger of infection from the sputum deposited in the street by consumptive patients visiting the clinic, the speaker had obtained by means of a letter of inquiry the views of the chiefs of each of the twenty special dispensaries for tuberculosis in the United States and Canada. There was an absolute unanimity of opinion that there was no danger to the public arising from the presence of such a dispensary in the community, that on the contrary, the special instruction and training given to the patients really diminished the element of danger to a minimum.

Dr. Horace Greeley of Brooklyn said that there were in Brooklyn from fifteen to thirty thousand persons suffering from pulmonary tuberculosis. He held that 10,000 of these were in a condition to be substantially benefited by the modern hygienic treatment, but of this number possibly one-half could not either be induced to leave the city or might be safely treated at home. About 2,000 of the remainder were independent and able enough to pay $5 or $6 per week in a model open-air institution on Long Island. It had been demonstrated that 80 cents per day was ample to pay the expenses in the care of patients in such a sanatorium. He remarked that the entire State of New York at present afforded free treatment for only 282 patients, for 110 it charged $5 per week, and for about 200 it charged from $10 to $35 per week. In these institutions during 1905, Brooklyn was represented by only nine patients. He accordingly argued the urgent necessity of a sanatorium. The Society selected a site on the middle and highest portion of the island, near Medford Station, where the Central Labor Union had purchased for it with $1,200 subscribed by 1,200 workingmen, a beautiful well-wooded tract of 65 acres. This locality offered the advantages of a summer temperature five degrees cooler than that of New York, while in winter it was warmer by fifteen degrees. Other advantages were its proximity to Brooklyn (50 miles), rendering it easy of access and also the presence of climatic conditions similar to those to which the patient hoped to return. On this site they intended to erect a two-story wooden building with extending wings, estimated to cost $50,000, containing 100 single rooms for patients, arranged along balconies extending from a central administration building. The exterior was to be of concrete, and the interior of hardwood lining, and was designed for subsequent indefinite extension.

Universal Depravity.—Dr. William Henry, an English physician, states, as the result of experiments, that, in all forms of animal life, insects included, exists the taste for alcohol. He says that fishes are the only "real teetotalers" in creation.

Therapeutic Hints.

Anesthetic for the Auditory Meatus.

℞ Acid carbolic liq.....0.5
Cocain. mur.
Mentholis .....aa 2.0
Spt. vini vect.....10.0

This mixture can be used, according to Hechinger, for the incision of furuncles, paracentesis of the drum membranes, etc., as the carbolic acid in it injures the epithelium sufficiently to allow the cocaine to be absorbed.—*Deutsche medizinische Wochenschrift.*

Impetigo Contagiosa.—Lau recommends white precipitate ointment, or:

℞ Zinci oxidi.....
Amyli .....aa 25.0
Vaselini flavi..... 50.0

or the following, used extensively in the clinic at Breslau, Germany:

℞ Sulphuris praecipitati..... 10.0
Amyli 20.0
Glycerini .....
Aquæ destillatæ.....aa ad 100.0
—*The Medical Herald.*

Hemoptysis.—Lawrason Brown advocates the use of the nitrites in this condition on account of their action in dilating the peripheral vessels, mainly of the head and neck and of the splanchnic area, causing a marked fall in blood pressure while the heart is accelerated. He suggests that the blood pressure be frequently observed, that morphine be used when necessary to quiet the patient, and so equalize the blood pressure, that sodium nitrite be exhibited to reduce when necessary the blood pressure, and that in case of sudden hemoptysis amyl nitrite be administered at once when possible to produce a marked fall in blood pressure and so aid in a temporary cessation at least of the hemoptysis. —*American Journal of the Medical Sciences.*

Bronchitis.—Eichhorst recommends as expectorants:

℞ Acidi benzoici.....0.3
Camphoræ 0.05
Sacchari 0.2

S. One such powder every two hours.

℞ Infus. rad. ipecac.....0.5:180.0
Pot. iodidi..... 3.0
Syr. simplicis..... 20.0

M. Sig. One-half teaspoonful every two hours.
—*Deutsche medizinische Wochenschrift.*

Intestinal Atony. For postoperative intestinal paralysis Anspach uses an enema composed of:

℞ Mag. sulph..... ℥ij
Ol. olivæ..... ℥ij
Glycerin .....f℥j
Ol. terebinth.....f℥ij
Aquæ, q. s. ad..... Oj

given through a rectal tube into the colon. If this is ineffectual, two hours afterward six ounces of glycerin is injected into the rectum.

In obstinate cases an enema of:

℞ Alum exsiccat.....℥ij-℥ij
Aquæ .....Oij

is ordered. Or, if the patient is able to take Epsom salt, this is given in drachm doses until effectual. In desperate cases a hypodermic injection of:

℞ Atropin. sulph.....gr. 1/150
Eserin. sulph.....gr. 1/100
Strych. sulph.....gr. 1/30

is given every three or four hours. When salts cannot be taken without passing a stomach tube, elaterium, gr. ¼, sometimes proves of value. Occasionally the enemas are more effectual when given with the patient in the Trendelenburg posture.
—*University of Pennsylvania Medical Bulletin.*

Epistaxis. Wiesner has found the following powder useful when snuffed up the nose:

℞ Antipyrini 0.50
Acidi tannici..... 1.00
Sacchari pulv. ad.....10.00
—*Pharmakologische Rundschau.*

Diarrhea in Children.—Perret suggests the following:

℞ Acidi lactici..... 3.0
Syr. mali cydonici..... 25.0
Aquæ destil.....100.0

M. et Sig. One teaspoonful every half hour to a child one year old. After the first year the dose is a tablespoonful. Another prescription is:

℞ Bismuthi phosphat solubil..... 2.0
Syr. simplic.....10.0
Aquæ destil.....90.0
Revue d'Hygiène et de Médecine Infantile.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the weeks ending September 1 and 8, 1906:

	Week of Sept. 1		Week of Sept. 8	
	Cases	Deaths	Cases	Deaths
Tuberculosis Pulmonalis...	374	148	329	168

Smallpox.....	3	—	2	—
Varicella.....	12	—	9	—
Typhoid Fever.....	94	20	139	13
Whooping Cough.....	26	15	30	9
Cerebrospinal Meningitis...	3	6	10	12
Malarial Fever.....	.....	.....	.....	.....
Totals	746	206	744	224

Deep Injections in Lues of Infancy.—Calomel injections have for many years been recommended and employed in children of one or two years of age. In their recent work ("La Syphilis") Drs. Barthelemy, Levy-Bing, and Schwaab report cases of lues in the new-born treated almost from the start with gray oil in 40 per cent. strength. One centigram of mercury was injected deeply into the muscles of the upper buttock every eight to fifteen days under all antiseptic precautions. A long, fine platinum needle is used. There is little or no pain, and if induration occurs it disappears by the time the next injection is given. There is no mercurial intoxication, and the good effects seem more lasting than when soluble salts are used. At the age of two months two centigrams a week or fortnight can be injected. A preliminary course of aqueous solution of biniodide (ten to fifteen injections) is perhaps preferable to beginning gray oil at birth.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending September 1, 1906:

SMALLPOX—UNITED STATES.

OBSTRUCTION OF THE COMMON BILE DUCT.*

WITH REPORT OF A CASE OF IRRIGATION OF THE HEPATIC-DUCT SYSTEM.

By JOHN F. ERDMANN, M.D.,

NEW YORK

CLINICAL PROFESSOR OF SURGERY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THAT all obstructions of the common bile duct eventually come to the surgeon for cure is a fallacious tenet, proven alone by numerous cases that are temporary only in their course. That all permanent and intermitting obstructions are distinctly surgical diseases, is a tenet well taken.

Some of the temporary causes of obstruction of the common duct are: Cholecystitis, with duct pressure by a distended gall-bladder; inflammatory changes in the duct or papilla, producing internal occiusive obstruction by means of infiltrate and swelling of the mucous membrane; foreign matter, as plugs of mucus, etc., and, finally, although most frequent, the passage of a stone through the duct itself.

In intermittent obstruction, we usually have a stone too large for passage through the duct, acting as a ball-valve. The symptoms appearing, when, for some reason, be it force from behind or irritation on the part of the duct, the stone is wedged or grasped in the distal portion, and the symptoms disappearing when the stone is released, either by relaxation of the irritable duct, or by some relief of the pressure from behind.

Permanent obstruction is due usually to one of two distinct processes, a stone impacted in the duct, or organic changes of benign or malignant natures. Of the latter processes, malignant changes are far more frequently found than benign stenosis.

The site of obstruction to be productive of a symptom complex sufficient to make a definite diagnosis, must be between the point of formation of the hepatic duct and the Vaterian papilla, and can be either external or internal in its relation to the duct lumen.

Among the external pressure causes of obstruction, we have malignancy of the gall-bladder and cystic duct, the outer walls of the common duct, the pylorus, the duodenum, and pancreas, while in the internal causes we must include, with stone, benign stenoses due to former ulceration within the duct, malignancy of the Vaterian papillæ, or of the duct itself, or malignancy of the duodenum encroaching upon the orifice of the otherwise healthy Vaterian papilla.

The symptoms produced by obstruction are readily classified by the cause of the obstruction. In the passage of a stone they of necessity are acute in all phases, while in malignancy a slow onset or chronic phase is given the picture. If due to a stone, pain varying in intensity is an ever-present symptom. This is usually located by the patient himself, in the epigastrium to the right of the median line, radiating into the shoulder-blade region and even into the neck, with very frequently some girdle manifestations. Point pressure pain is elicited over the course of the duct, a point somewhat internal to that in cholecystitis.

Nausea and vomiting are often an accompanying manifestation at the onset. The temperature is usually not elevated until later complications arise, such as cholangitis, etc., although I have seen it in the onset 103°, and subside in a day or two. Evidences of jaundice appear within a few hours to several days; jaundice is never a factor in cholecystitis, except as a result of pressure on the common or hepatic ducts. The stools soon lose their characteristic color and become of a light clay or putty shade. The urine presents evidences of bile, from a slight chemical trace to profound ocular manifestations. The skin, with varying degrees of jaundice, itches usually, and occasionally to such a degree as to be almost unbearable; jaundice appears first in the sclerotic of the eyeball.

The liver, while not affected at first, soon becomes engorged, and may in a few days become distinctly palpable beyond its normal relations. Digestive disturbances, chiefly referable to the stomach, arise early. Finally a distinct loss in weight is readily demonstrated.

Should the obstruction be of the intermittent variety, all the symptoms subside, either in part or entirely, only to recur when the stone is again wedged or incarcerated.

Should cholangitis arise, the clinical picture rapidly takes on a serious phase. The temperature and pulse rapidly rise, the patient has an additional facial appearance, that of an hectic flush, and a general septic evidence becomes a noted factor. The pain, instead of being limited to the duct region, spreads to the liver area, and a greater or less degree of coma is present. This latter may be present in cases where no cholangitis exists.

There should be no difficulty in arriving at a diagnosis of stone in these acute cases, except at the time of the onset of pain, as occasionally the pain is not of the characteristic variety described above, and therefore may be questioned as being that of either acute pancreatitis, gastroduodenal perforation, or a high-placed appendix undergoing an attack.

In the slow or chronic cases one can readily be led astray in the diagnosis, and great care must be taken to differentiate between chronic pancreatitis with gradual obstruction of the common duct, malignancy, or inflammation of any portion of the gastro-intestinal tract capable of producing pressure upon the common or hepatic ducts.

Should the gall-bladder be enlarged in the chronic cases, so as to be palpable, a marked suspicion of

*Read before the Practitioners' Society of Eastern Monmouth, at Elberon, N. J., June 14, 1906.

malignancy is in order. Courvoisier's law that in malignancy or external pressure to the duct, an enlarged bladder may exist, and that an obstruction by stone is usually accompanied by an atrophied or contracted bladder, holds good in a fair percentage of cases. Recently (see case cited) I had a patient, a girl of seventeen, with both obstructive cholecystitis and cholangitis, in whom the gall-bladder was enormously dilated.

Presuming that all medical aid has been given without result, or that the symptoms are of such urgency as to demand immediate surgical interference, the condition then narrows itself to a question of surgical technique and subsequent treatment.

My custom in exposing the duct is to make the incision over the right rectus, splitting the fibers in the middle and internal, or middle and external thirds, for a distance sufficiently long to explore the duct. If the stone is located or adhesions demand the incision is then rapidly enlarged so as to give ample working room. The customary pillow under the back, depending upon the accessibility of the duct, may or may not be used. When the site occupied by the stone has been cleared of such adhesions, etc., as are necessary, and all the surrounding viscera thoroughly protected by salt solution pads, a traction suture is passed through the walls of the duct at about the upper limit of the intended incision into the duct. The stone is then steadied by two fingers in the foramen of Winslow behind or below the duct, and the thumb above or in front, and an incision sufficiently long to allow of the expulsion of the stone or stones is made. After the expulsion of the stone, and proof by search that no other stones are present, a fishtail rubber tube, with from one to three openings and about ten or twelve inches long, is passed into the duct in its proximal direction, for its lower three-quarters of an inch, sufficiently to bury the apertures only. A suture of chromic catgut is then taken through both edges of the duct and includes a portion of the tube above the openings. This is tied and assures us of no slipping of the tube until the suture is absorbed. When this latter occurs, a safe way is established for further drainage, if necessary. As many more sutures are taken as may be required to close the gap made in the duct. A cigarette drain is then placed down to the site of the suture line as a precaution against leakage. The protection pads are removed after thoroughly sponging out the area with salt sponges, and the abdomen closed to the drainage site.

The removal of a stone is not always so simple a procedure. Should the stone be impacted in the lower quarter to half inch, one of two procedures can be undertaken. The transduodenal route of McBurney, or the retroduodenal method advocated and described by A. A. Berg (*Annals of Surgery*, August, 1903), and C. M. Cooper, who reported three cases successfully done by this method (*ibid*, September, 1903). Greater safety lies in the latter method, as none of the dangers of infection by intestinal contents arise that are more than possible by the McBurney transduodenal route.

It will be recalled that the tube in the duct is passed in but about three-quarters of an inch and has several perforations. These perforations allow of a certain amount of bile to pass through the distal portion of the duct in case its caliber becomes diminished so as to hug the drainage tube, while the excess of bile must perforce drain through the rubber tube. This drainage is carried off by attaching a tube sufficiently long to pass over the edge of the bed into some receptacle, usually a bottle, in which the discharge can be seen and measured. When the physical character of the bile begins to assume a normal aspect, I am in the habit of pinching the tube an hour out of every eight for the first day, then two hours at a time, etc., so that in a short time, at the end of the fourth or fifth day of apparent normal bile, the tube, if still in, is pinched or shut off for about twelve hours out of twenty-four. I deem this an essential procedure, as the system absolutely demands this great secretion for the proper metabolism of the food intake.

It has been, and is yet, a custom of mine, during the first few days, to give oxgall in doses of five to ten grains every four hours, and I feel that noted benefit is derived in those cases where the quantity of drain seems excessive. After the drainage tube comes out (from ten to twelve days) the skin of the abdomen requires, in most cases, constant attention to prevent a most pernicious dermatitis. This is readily accomplished by the use of boric or ichthyol ointment, and cleanliness by frequent dressings. The fistula usually closes in from two to three weeks.

In cases of malignancy and stricture, should the growth or stenosis be distal to the cystic duct and nonremovable, then a cholecystenterostomy is in order, while if it is removable, excision with end-to-end, or end-to-duodenum, etc., anastomosis should be done. If it be proximal to the cystic duct, operative procedure becomes almost impossible.

The history of the case referred to above is of such interest from the viewpoint of the age of the patient, the enormous dilatation of the common duct, and the extent of the operative procedure, that I include it as a most interesting conclusion to this paper.

A girl, seventeen years of age, of Russian Jewish parentage; no history of typhoid fever; always constipated; perfectly well previous to her landing in America two and a half years ago; a victim of favus; entered the hospital on April 1 of this year, and gave the following history: She had been jaundiced for four weeks. Has had occasional cramp-like pains in the upper abdomen on the right side. On the day before admission she had an attack so severe in its character and duration as to necessitate urgent attention.

This additional history was obtained subsequent to the operation: On coming to America two and one-half years ago, she was ill for six weeks; had amenorrhea and pains similar to the present; no jaundice noticed. About two years before admission she was jaundiced for about one year. During this time she had a dull, aching pain in the right hypochondrium, which was occasionally intensified into an acute stabbing pain in the same region. This was followed each time by dark blood in the fecal discharges. She does not remember the color of the stools or urine. No gallstones were noticed in the stools. During this time she says she vomited about three times a week, and each time the vomiting was followed by relief. Had to leave her work at times and remain in bed on account of the pain; would feel warm and cold, and drink much water. Has been more or less jaundiced ever since that time, and has never been entirely well. These attacks of jaundice were accompanied by profound itching of the skin. She says the pain in the back, directly behind the gall-bladder, was more severe than in front. All this time she has had severe headaches and indigestion, "yellow vision," and black spots before the eyes.

Upon admission the patient was delirious and in coma. Well nourished, deeply jaundiced skin and conjunctivæ. Scalp, favus over the greater portion. Chest, negative. Abdomen, tenderness and rigidity

over the gall-bladder region; also markedly tender spot about one inch above the umbilicus and somewhat to the right. Liver dullness four inches below the costal arch and extending downward over what appeared to be an enlarged gall-bladder. Pulse, 106 to 120; temperature, 103.4° by mouth. The temperature on April 2 fell to 99.5°, pulse 88. On the following day the temperature was 104.6°, pulse 152; delirium and coma were present, and the patient looked septic.

Operation was done within forty-eight hours of admission and in the third day of the attack. Upon exposing the liver, it was found to be nodulated and congested to a very deep degree, exceptionally hard to the touch, and greatly enlarged. The gall-bladder was about eight inches long and three inches in diameter at its fundus; tense, and buried in an omental mass, highly discolored and presenting spots of color through its serous coat that were considered (and so proven after opening) gangrene of the mucous coat.

After liberating the bladder from its omental encapsulation, a stone was palpated in the cystic duct. By following the duct to the common, a mass of stony hardness, over three inches in length and larger than an ordinary thumb, occupied the site of the common duct. Cholecystectomy, choledochotomy, etc., were decided upon. While releasing the gall-bladder from its liver sulcus, it ruptured, expelling fully ten ounces of the most foul smelling and appearing contents that I've ever met with. The bladder was then rapidly excised, and a stone about three-quarters of an inch long by a half inch in its largest diameter was removed from the cystic duct. Two pairs of forceps grasped the sides of the cystic duct, which was then split to the common duct. This latter and the hepatic were then split for a distance of an inch and a half. Two stones, seven-eighths of an inch in diameter and measuring two inches long, were expelled, while a third one was located in the pancreatic and retroduodenal portion of the duct. This was also seven-eighths of an inch in diameter and a fraction over an inch long. This latter stone was so thoroughly fixed that great difficulty in its expulsion was met with. Owing to edema, adhesions, etc., neither the transduodenal nor the retroduodenal operations could be done. Having a large duct, and a large opening in it, I was able to fragment the stone with a small instrument introduced into the duct, part of the stone being pushed through the papillary opening, and the remainder delivered by scoop through the choledochotomy wound.

Examination of the hepatic ducts was then made with the little finger. These were blocked with stone and biliary detritus. Upon removing these materials there was a profuse gush of the same foul-smelling and appearing material as was present in the gall-bladder.

Reexamination of these ducts proved the presence of more of this same material. A blunt curette was then passed into both right and left ducts, bringing out quite a quantity of detritus, and then, although I'd never seen nor heard of irrigating the liver ducts, I introduced a quarter-inch irrigating tube and flushed the liver with saline solution through these ducts. During this flushing process, one could readily see the liver, which had subsided considerably as a result of the emptying of the ducts, rise and fall with the entrance and discharge of the solution.

A tube was sutured into the duct, several sutures taken to close the balance of the incision in the duct, and then a deep incision was made into the liver substance of the superior surface of the right lobe, for about two and a half inches in length. This was done as an extra means of drainage, and was accompanied by a fair hemorrhage, but was readily controlled by gauze. The exposed area was sponged with salt solution, and the wound closed to the drain site. Time occupied, one hour and ten minutes.

The temperature dropped to 100° by rectum, and remained on a line between 99.4° and 100.4° for six days, then became normal and remained so except for an occasional constipation rise of one degree. Fifteen ounces of dirty, foul-smelling bile were collected the first fifty hours.

April 7. Patient doing nicely; bile clearing up.

April 11. Stools, which were clay color before operation, still so. Tube came away; patient passed fragments of stone by the bowel, that had been forced through the papillary opening.

April 17. Stone size of pea discharged through the wound. This must have come from the liver. Stool well formed and yellow. Sinus in abdominal wall doing well.

April 22. Patient sat up for the first time, that is, on the nineteenth day after the operation.

May 5. Patient was discharged at her own request, thirty-three days after the operation.

The urine varied in specific gravity, from 1030 to 1016; it was acid except on April 5 and May 4, when it was found to be alkaline. Some blood was found on April 4. The blood count on April 3 showed white blood corpuscles, 20,000; polynuclear, differential, 81 per cent.

60 West Fifty-second Street.

LUPULIN IN THE TREATMENT OF GASTROINTESTINAL DISEASES.*

By HEINRICH STERN, M.D.,

NEW YORK

Lupulin, although officinal, is a drug which is not extensively employed nowadays. To be sure, there are many malt liquors, beer especially, that contain hops and which are largely consumed as appetizers and stomachics. However, the proportion of hops found in the malt beverages is so small that, generally speaking, a lupulin-action cannot be obtained even if an individual imbibes rather large quantities of any brew. In such instances, the alcohol-action makes itself evident long before that of lupulin can possibly be felt. Furthermore, quantity and quality of lupulin differ widely in various specimens of hops, and thus it may happen that but infinitesimal amounts of it may be contained in an entire liter of beer. Hence, if we wish to obtain the lupulin-action there is nothing left to us but to prescribe the drug in its pure state.

Lupulin is a fine brownish-yellow dust which covers the inner side of the scales of the flowers of humulus lupulus. Under the microscope the powder is seen to consist, according to the P. B. of 1885, of minute, somewhat globular, top-shaped, reticulated, translucent, shining glands. These glands contain hop-resin, hop-oil, bitter principles, lupulic acid, etc. Lupulin burns readily, and it contains the greater part of the volatile oil to which is chiefly due the peculiar aroma of hops. In unripe hops little or no lupulin is present, hence the absence, or deficiency, of hop-aroma in beer brewed with it.

Various samples of hops contain various amounts

*Read at the meeting of the Medical Association of the Greater City of New York, June 11, 1906.

of lupulin. Its amount may fluctuate between six and twenty per cent. Hops cultivated in Japan from European seeds are the poorest in lupulin. European hops grown in the best hop-countries exhibit from twelve to fifteen per cent. of lupulin. A sample of hops from Wisconsin yielded twenty per cent. of lupulin.* The proportion of lupulin depends seemingly upon the frequency of sunny days during the ripening season.

Lupulin, however, does not exhibit a definite composition. Its various constituents differ in different specimens. This is especially the case with the absolute and relative amounts of the individual components. Thus it is the quality, and not the quantity *per se,* on which depends the value, and particularly the therapeutic import, of lupulin.

That there exists a great discrepancy as to the therapeutic efficacy of the various lupulins of commerce, I think I was the first to demonstrate (Transactions of the Manhattan Clinical Society, April 1903, *Medical Standard,* 1904). The results obtained by different lupulins are not uniform. A sample of fresh lupulin obtained soon after the hop harvest, is much more efficient in therapeutic respect than one which is some months old. Again, if lupulin is kept over summer, it is always rendered more or less useless for therapeutic purposes. As a matter of fact, all specimens of lupulin of the previous harvest, made use of by me for therapeutic investigation, proved almost entirely inert. This was even the case when the fresh product has proved of exceptional efficiency. Lupulin, even when kept in an air-tight container, soon attains a cheesy odor. This ensues especially if it had been kept in a warm place. This odor of decomposition is due to the production of valeric acid. The latter was formerly thought to be the result of the oxidation of hop-oil; however, it seems more likely that it originates from the oxidation of the bitter principles contained in lupulin. It will be found that lupulin, or that what is usually sold under that name by pharmaceutical houses, is in almost every instance a more or less deteriorated article the therapeutic action of which—at its best—resembles that of a weak solution of valeric acid. In order to obtain a satisfactory lupulin-action, it is, hence, imperative that the product is to be obtained from commercial houses importing it in large quantities for brewers' use, and that the air-tight vessel containing it be kept in cold storage, and not on the shelves of drug-shops for months and years, as is the case generally, before it is prescribed.

Lupulin contains a brown insoluble resinous matter, *lupuliretin,* $C_{10}H_{18}O_4$, *lupulinic acid,* $C_{48}H_{82}O_{19}$, *lupulic acid,* $C_{50}H_{70}O_8$, and occasionally an alkaloidal substance, "*lupuline.*" The lupulin-action seems to depend upon its content of lupulic acid. If the acid is exposed to the air, its colorless prisms change rapidly to yellow, its upper layer attains resinous consistency and a decomposition-odor constiting of valeric acid and aldehydes is being produced. This conversion ensues ever more rapidly if a small amount of an alcoholic solution be placed on a watchglass and allowed to evaporate in the air. Lupulic acid derived from old hops or lupulin does not crystallize readily. The resinous substance due to oxidation of the acid has certain antiseptic properties: it prevents, more or less, lactic acid fermentation, but exerts no influence upon acetic acid fermentation or upon yeast-activity. Dreser (*Pharmaceutical Journal,* XVII, Allen) determined that 0.025 gram unconverted lupulic acid in alcoholic solution acted as a fatal poison in frogs and guinea-pigs. In frogs, it called forth paralysis of the central nervous system and of the heart. In warm-blooded animals the acid gave rise to a very pronounced acceleration of the respiration. The resinous oxidation-substance practically exhibited no poisonous qualities. F. Davis (*ibid.*) injected into the jugular vein of a cat a watery solution of 0.18 gram of crystals, obtained by him by extraction with ether of green strobiles of hops, which produced death in seven minutes. The animal seemingly had no pain, but a peculiar twitching of the muscles could be noticed.

A substance of alkaloidal nature, "lupuline," which is said to exhibit narcotic qualities, was isolated from hops some years ago. This body does not seem to be of constant occurrence, as very few investigators have been able to obtain it. In the finer grades of hops it does not seem to be present at all. Another alkaloidal body, pretended to be obtained from American hops, and marketed under a trade name, on analysis proved to be a mixture of morphine with another alkaloid, seemingly atropine (*Pharmaceutical Journal,* XVI, Allen).

The lupulin which I found the most active and trustworthy in my physiological and clinical experiments proved to be that from Saaz hops. Saaz is a little town in the Bohemian hop-belt. I do not know whether the hops of Saaz are any better than the hops of neighboring quarters, but I know from experience that the lupulin-producers of this town understand more about the handling of their product than do the growers in other sections of the hop-country. In my studies of lupulin, that from Saaz was depended upon for the last couple of years.

In the following I limit myself to a discourse of the therapeutic influence of lupulin on disorders of the alimentary tract, my associate at the Institute for Medical Diagnosis and Research in the City of New York, Dr. Thomas F. R. Reilly, having already reported our experience with the drug in a variety of disturbances of other organs. (American Medical Association Section on Pharmacology and Therapeutics, 1905.)

Diseases of the Stomach.—Lupulin finds a special indication in the functional disturbances of the stomach; in sensory, as well as motor and secretory neuroses and in neurasthenia gastrica.

The gastric neuroses are almost always expressions of general affections like neurasthenia and hysteria. They are but rarely of independent occurrence, and remedies which act locally only have, if at all, limited ameliorating influence. Lupulin is frequently a modifier of the general nervous system. It is in part a symptomatic, in part a causal remedy.

Among the gastric neuroses of sensation lupulin is of value in the treatment of *nervous anorexia.* This condition which may last for protracted periods, occurs mostly in women and results in emaciation, loss of bodily vigor and resistance, and often anemia. The drug may be prescribed as follows:

℞ Lupulin ..... 0.3 gram (5 grs.)
D. t. dos. No. C (100) in caps. gelat.

Sig. From one to three capsules one or two hours before meals with carbonated water.

If a more energetic local action is desired, the following combination will be found useful:

℞ Lupulin ..... 0.3 gram (5 grs.)
Berberini phosphatis. .... 0.03 (gr. ss)
Capsicini..... 0.0075 (1-8 gr.)
Ft. d. t. dos. No. C in caps. gelat.

Sig. From 1 to 3 capsules half an hour before meals.

*The pertaining data are obtained from "Commercial Organic Analysis," by Alfred H. Allen, Vol. III, Part 3.

In the treatment of nervous anorexia and other functional gastric disturbances I have often found the following combination of particular value:

℞ Lupulini 0.2
Condurangini 0.01
Cinchonidini 0.05
D. t. dos. No. 100 in caps. gelat.

Sig. 2 capsules half an hour before meals, to be followed by one or two teaspoonfuls of whiskey or brandy.

Hyperesthesia of the gastric mucosa, not infrequently associated with anorexia of a foregoing variety, occurs often as a neurosis, especially in chlorotic female individuals. In this condition there exists an augmented sensibility of the gastric nerves which may cause painful sensations upon very slight digestive or psychic irritation. The patients experience painful gastric fullness and nausea. Normal gastric chemism is characteristic for this condition—a fact by which a differential diagnosis may be readily established.

To overcome these painful sensations I am in the habit of prescribing the following:

℞ Lupulini 0.25
Argenti nitratis ..... 0.005 (1-12 gr.)
D. t. dos. No. 30 in caps. gel.

Sig. One of two capsules before meals together with half wineglassful of luke-warm water.

This combination continued for some time suffices very often to relieve the burning or gnawing gastric pain. In a few instances it is necessary to incorporate with it small doses of codein or extractum belladonnae fol. alcohol.

Another good combination affording relief of gastric hyperesthesia is the following.

℞ Lupulini 0.5
Camphoræ mono-brom..... 0.15—0.3
M. et ft. pulv. d.t. dos. No. XXX.

Sig. One powder before meals in wafers.

It must be understood, of course, that dietetic and other measures must often be instituted along with the medicinal treatment.

In the most painful of all gastric neuroses, *cardialgia* (gastralgia, gastric spasm, gastrodynia) lupulin is a valuable remedy provided the gastric pain is the consequence of neurasthenia, hysteria, chlorosis, or general weakness. Lupulin exerts no or but limited influence upon cardialgias due to central organic nervous disease, or to organic gastric or intestinal affections. During the acute cardialgic attacks, when severe, medication should not be administered per os. This would preclude the employment of lupulin. However when the attack is less severe, and particularly in the intervals, lupulin proved a very efficient therapeutic agent.

In the less severe forms of cardialgia, which, fortunately, are those most frequently met with, lupulin in gram doses (in wafers or divided in capsules), to be repeated, if necessary, every hour, will be found of service. The addition of small doses of codeine will often, though not always, enhance the efficacy of the drug. The administration of spiritus chloroformi or spiritus ætheris compositus, together with lupulin, does not interfere with the activity of the latter. The influence of both chloroform and ether is a transient one, while that of the lupulin is enduring for decidedly longer periods; however, its sedative effects are not exerted as quickly as are those of chloroform or ether. Hence, for immediate effects, preparations of chloroform or ether, for longer lasting effects, lupulin, are the remedies.

When it seems advisable not to administer any drug by the mouth, lupulin may be given in the form of suppositories. These may be made with oleum theobromæ. A more suitable menstruum, however, one which probably would preserve the qualities of the lupulin for a considerably longer period, I think, would be a glycerogelatinous hollow cone in which the drug is introduced. The following formulæ answer very well:

℞ Camphoræ
Lupulini .....aa 5.0 grams.
Ext. belladonnæ..... 0.15
Olei theobromatis q.s.
M. et ft. suppositoria No. X.

Sig. One suppository to be inserted into the bowel every two hours.

℞ Lupulini ..... 5 grams.
Extracti cannabis Indicæ..... 0.3
Olei theobromatis q.s.

Sig. Insert one into the bowel every two hours.

℞ Lupulini 5.0
Ext. physostigmatis 0.2
Ext. belladonnæ alc..... 0.1
Olei theobromatis q.s.
M. et ft. supp. No. X.

Sig. One suppository every three to four hours.

The neuroses of gastric motility, increased as well as diminished peristalsis, often yield to lupulin. This is especially the case with the various forms of nervous vomiting, the common, the periodic, and the juvenile types. In these instances lupulin has a decidedly more lasting effect than either bromides or valerianates and does not give rise to secondary trouble as these other drugs are apt to do. Generally speaking, lupulin may be given in nervous vomiting in the same doses and combinations as in cardialgia. In vomiting of pregnancy I have recommended a combination of menthol and lupulin to some obstetricians who have employed it to advantage in many cases. Three to ten drops of a 25 per cent. ethereal solution of menthol are added to 0.5-0.75 gram lupulin previously placed in a wafer. This dose may be repeated, when necessary, every 3 or 4 hours.

In aerophagia and gastric spasms the drug serves a good purpose. Besides the medicinal treatment, other therapeutic measures may, of course, be instituted. In atony—that is, in diminished gastric motility without demonstrable anatomic changes—lupulin acts as a gastric stimulant. The fact must not be lost sight of that lupulin is not only a symptomatic remedy, but that it may also alleviate or eradicate the cause of certain alimentary disorders, as it stimulates the general and local circulation and improves the tone of the stomach and intestinal tract. The best suited lupulin combinations for this form of gastric atony are those aluuded to when speaking of nervous anorexia.

Gastric secretory neuroses of all forms and degrees are usually greatly benefited by lupulin. In hyperchlorhydria a systematic effect is to be obtained. For that purpose the dose should be from 0.75 to 1 gram. In subacidity or anacidity of nervous origin the local action is the one which is primarily indicated. A smaller dose, as a rule, suffices for that purpose. In cases of hyperchlorhydria or chronic hypersecretion, extract of belladonna or atropine may be administered with the lupulin, but only for limited periods. I find that lupulin alone, if given in sufficient doses, will ameliorate gastric neuroses in most instances. In cases of deficient acidity lupulin may be combined with such agents as recommended for nervous anorexia or with bitter stomachics. The latter may be taken separately. In hyperesthesia lupulin may be given before and after meals.

The most frequent gastric neurosis is *neurasthenia gastrica,* the so-called nervous dyspepsia. It is a combination of the various neuroses spoken of in the foregoing. Lupulin is indicated in the same manner as it is in the component neuroses. It may be advantageous to combine with it some preparation of iron, or other tonic remedies. I have frequently used one of the following formulæ:

℞ Lupulini 0.15
Ferri et quininæ citratis..... 0.1
D. t. dos. No. C in caps. gel.
Sig. Two capsules before meals.

℞ Lupulini 0.15
Ferri et strychninæ citratis.
Cinchonidinæ sulphatis .....aa 0.05
D. t. dos. No. C in caps. gel.
Sig. Two capsules three times a day.

℞ Lupulini 0.15
Massæ ferri carbonatis..... 0.1
Extracti nucis vomicæ..... 0.015
M. d. t. dos. No. C in caps. gel.
Sig. Two capsules before meals.

In diseases of the stomach arising on an *anatomical basis,* lupulin, although not to the extent as in the functional disorders of that organ, may frequently be employed to advantage. In the treatment of any of the three stages of *chronic gastric blennosis,* for instance, it is of special value, by slightly stimulating the mucosa, by improving the tone of the entire organ, by averting the production of undue amounts of mucus, by checking lactic acid and, to a certain degree, butyric acid formation, and by its sedative effects upon stomach, intestines, and the heart.

For the same reasons I have found the drug a valuable standby in *gastrectasia* both of mechanical or atonic origin. In many cases of moderate gastric dilatation, besides regulation of diet and certain adjuvant measures, I did not need to prescribe anything but lupulin and an occasional laxative. If the drug be administered in a liquid menstruum, as for instance in vinum condurango, or in mistura rhei et sodæ, small amounts should be ordered at one time and the patient be instructed to agitate the mixture before partaking of it.

Diseases of the Intestines.—The intestinal affections in which lupulin is particularly useful, are, as among the diseases of the stomach, the neuroses, the functional disorders. Sensory, as well as motor and secretory neuroses, are beneficially influenced by the drug, probably in a higher degree even than are the analogous conditions prevailing in the stomach. My observations as regards lupulin in intestinal diseases prompt the following statements: That if administered by the mouth, the drug should be given in capsules, that the dose should be one and a half or two times that which is recommended for the analogous gastric disease, that in disease of the colon or rectum suppositories (hollow glycerogelatin cones if possible) are to be preferred, and that the drug may be given for protracted periods without causing cumulative or other deleterious effects.

The main sensory disturbance of the intestines, *enteralgia nervosa* or neuralgia of the intestine, which according to Nothnagel is a genuine neuralgia of the mesenteric plexus, is often tractable to lupulin. Sometimes, however, enteralgia, which has nothing in common with the condition characterized by colic, appears to be a local enunciation of a neuropathic constitution. Again, in such instances, lupulin has also rendered me good service.

Opium is distinctly contraindicated in enteralgia on account of the production of obstipation, which latter may give occasion to colicky pains. I am in the habit of prescribing in the milder cases:

℞ Lupulini 0.15
Acetanilidi 0.1
Ft. caps. d. t. dos. No. L.
Sig. Three capsules every two to three hours.

Or,

℞ Lupulini 0.3
Hyoscyaminæ salicylatis 0.0005
Ft. caps. d. t. dos. No. XX.
Sig. One capsule every three to four hours.

In severer instances of enteralgia nervosa I have found of benefit:

℞ Lupulini 0.25
Codeinæ sulphatis 0.015
Atropinæ sulphatis 0.0003
Ft. caps. d. t. dos. No. XX.
Sig. One capsule every hour if necessary.

When the pain becomes less intense the lupulin-acetanilid capsule may be substituted for the last-named combination.

The *motility neuroses of the intestines,* as nervous diarrhea, peristaltic intestinal unrest, enterospasm and nervous flatulency are all more or less beneficially influenced by lupulin.

Most cases of *nervous diarrhea* are not solely due to hypermotility, but also to secretory anomalies of the intestines. The treatment of this very inconvenient disturbance should be principally dietary and physical. If a case is rather stubborn absolute rest in bed for from three to five weeks should be insisted upon. Opium, it is true, may cut short an individual attack, but it should be resorted to in extreme instances only, as it is liable to make opium-habitués, especially among women. Occasionally lupulin may be given together with tannigen, tannoform, tannopin or tannalbin. I have frequently ordered for nervous diarrhea:

℞ Lupulini
Strontii bromidi .....aa 0.15
Ft. caps. d. t. dos. No. L.
Sig. Two capsules three to five times a day.

℞ Lupulini 0.3
Pulvis ipecacuanhæ 0.02
Ft. caps. d. t. dos. No. XX.
Sig. One capsule four to six times a day.

Lupulin in combination with camphor and ext. belladonnæ or with ext. cannabis indicæ, as recommended for cardialgia, will be found very useful.

Constitutional treatment, of course, ought not to be neglected. According to indication, iron, arsenic, or quinine should be administered for protracted periods.

The excessive intestinal peristalsis of neuropaths, *peristaltic unrest* or *tormina intestinorum,* apart from constitutional therapy, is best treated by a mild nervine-narcotic like lupulin. Lupulin in daily doses of from two to four grams, or in combination as given for nervous diarrhea, will often overcome this condition. In the treatment of *enterospasm* lupulin is given in the same manner as in enteralgia or nervous diarrhea.

Nervous flatulency, which always occurs on an hysterico-neuropathic basis, is often directly due to the accumulation of swallowed air in some part of the intestinal tract, as pointed out by me some time ago (The Clinical Importance of Aerophagia, *New York Medical Journal,* Feb. 20, 1904). Lupulin with bromides is probably better in ameliorating the acute condition, as well as the underlying neuroses, than any other combination of drugs I am acquainted with. In some cases an easily digestible preparation of iron will be found a good therapeutic adjuvant. Carminatives, considering the etiology

of the disturbance, have very limited influence in overcoming nervous flatulency.

Of the *secretory intestinal neuroses* it is especially the *mucous colic,* colitis membranacea, in which lupulin, alone or in combination, has proved itself of distinct value. The condition is mostly met with in neurasthenic females; it is, however, of not infrequent occurrence in the non-neurasthenic enteroptotic individual. The affection may just as well be classified among those with an anatomical basis as among the secretory neuroses. For our purposes, however, the classification makes little difference. Of course, medicinal treatment avails the very least in this affection. We have to depend upon dietary regulation, a well-fitting adominal supporter that supports and high rectal medicated injections. An infusion of hops, alone or together with one of chamomile flowers, should be tried in every instance of mucous colic. Lupulin in this affection should be only administered in suppositories which are to be introduced high up into the rectum. There is no doubt that lupulin exerts a stimulating influence upon the colonic mucosa which enhances the latter's tone; at the same time, it reduces the nervous irritability and reflex contraction by its sedative and narcotic action and limits by its antifermentative qualities intestinal fermentative processes. As repeatedly stated, the suppositories, if possible, should have a glycerogelatinous mass for a base which melts at body temperature. This mass should be molded into cones, the hollow inside of which is to serve as a receptacle for the drug or drugs to be administered. There should be receptacles large enough to hold one or two grams of powdered material or prepared mass.

A combination which I find very useful in materially reducing tenesmus and pain, or averting paroxysms altogether, and which, at the same time, diminishes or entirely suppresses the pathological amounts of mucus and the formation of intestinal casts, is the following:

℞ Argenti iodidi 0.2
Pulvis belladonnæ foliorum..... 0.1
Lupulini 1.0
Ft. supp. (glycerogelat.) d. t. dos. X.

Sig. One suppository at bedtime, if necessary one also at midday, to be inserted into the rectum as high up as possible.

In intestinal diseases with an anatomical basis lupulin is often a symptomatic and occasionally a curative remedy. This is particularly the case in inflammatory conditions of the intestinal mucosa. Of course, in acute instances there is less occasion to test the value of this drug than in chronic cases. However, in *acute enteritis,* after complete evacuation of the bowels has been established, when a sedative-narcotic-tonic medicine is indicated, lupulin alone or in combination with opium, will render very good services. In children and the aged, periods of life in which there exists pronounced intolerance for opium or its derivates, lupulin will be found the supreme remedy. It may be combined with opium or any of the modified tannin preparations, with preparations of bismuth, with camphora monobromata, etc.

It is to be understood that in the treatment of *acute* as well as the *chronic* forms of *enteritis,* diet regulation plays the most important rôle. Medicinal treatment, especially symptomatic treatment, is often the least important because it is also the least effective. Opium, which may be very valuable in acute enteritis, has no place at all in the treatment of *chronic enteritis,* firstly, because if given for protracted periods it renders the patient an habitué, and secondly, by the artificial retention of the dejecta without diminishing the intestinal secretion, it causes a still further irritation of the diseased mucosa, the inevitable consequence of which is renewed and more violent attacks of diarrhea. The management of chronic enteritis proves frequently the task of Sisyphus. Most good yet do nonirritating astringents and antifermentatives in combination with a sedative-neurotic-tonic like lupulin. If the inflammatory process has extended to the colon, enteroclysis with an infusion of hops or with astringents (argentum nitricum in solution of from 0.2-1.0%). and the administration in suppositories of lupulin and astringents, will often yield satisfactory results.

In *proctitis lupulin* introduced by means of suppositories, together with argentum nitricum, or acidum tannicum has always rendered me good service. It promptly allays tenesmus and pain without producing untoward after-effects.

The foregoing account comprises the extent of my own observations concerning the employment of lupulin in gastrointestinal practice. It evidences that lupulin is not only a palliative, symptomatic, but oftentimes also a curative agent. Its employment, even for protracted periods, is never followed by undesired after-effects, which latter are so common with many remedies employed for similar purposes. I had no occasion to prove the therapeutic value of lupulin in a large series of cases of enteric fever. It is probable that this affection will be beneficially influenced by it. The drug, on theoretical grounds, deserves also an extensive trial in dysentery.

SOME OF THE FACTORS THAT PREDISPOSE TO PHTHISIS.

By L. P. BARBOUR, M.D.,

LOUISVILLE, COLORADO.

Since Koch's epoch-making discovery of bacilli as the immediate cause of tuberculosis in all locations, there has been too little investigation of the influences that predispose to this disease. Not one iota of the energy given to lessening the spread of these insidious bacteria need be abated; but coordinately with this movement there ought to be more effort to lessen the predisposing causes. It is a broad field filled with intricate scientific problems and with threads of thought leading in various directions.

The study of immunity is involved in a study of predisposition. To say that a predisposition to tuberculosis exists, is only another way of saying that there is an absence of immunity. We may attack the problem by asking what causes immunity. And is there any immunity to infection by the bacilli tuberculosis? Immunity is a condition whereby the organism is able to resist successfully an invasion of specific germs. It may be natural, acquired, or artificial. Natural immunity is the natural resistance of the organism to disease. Most animals, for instance, have a natural immunity to syphilis. Immunity to some diseases is acquired by a previous attack. One who has had measles has acquired immunity to that disease. Artificial immunity to any disease is produced by inoculation with the virus of that disease. Acquired and artificial immunity may be classed together as specific immunity, as such immunity is always the result of the specific disease or virus. Do any of these forms of immunity exist in the human family regarding tuberculosis?

Again immunity may be relative or absolute. There is probably no absolute immunity to tubercu-

losis, so far as man is concerned, either natural or acquired. No one has such physiological vigor or specific resistance as to resist a sufficient number of bacilli sufficiently long continued. Moreover, there are probably no animals that are absolutely immune to tuberculosis. There are some that have a high degree of relative immunity. Those animals that are quite susceptible to the disease show under some conditions a relative immunity; perhaps it would be more accurate to say that they have less susceptibility. Rabbits, for instance, die much more quickly from a given amount of infective material when closely confined in a dark place than when in a light, open, airy space. Dogs show less resistance when poorly fed than when well cared for and fed on plenty of raw meat. This has been a matter of experimentation.

Has mankind any immunity? There is a universal belief that some people have decidedly more resistance than others, and this general opinion is without doubt correct. These people have a certain degree of immunity. Further, the same individual has at times a higher degree of immunity than at other times and conditions. The man living a reasonably active outdoor life will resist more than when closely confined in unhygienic surroundings. So, too, he will succumb more quickly to the same infection immediately after severe sickness, etc. These things lessen the degree of natural immunity. They predispose to phthisis.

Specific Immunity.—While this has little bearing on predisposition, yet it is one of the interesting threads of thought that come into the discussion. There is evidence to show that quite a degree of specific immunity may be given to animals by tuberculin injections, by the use of antituberculous serum or by inoculation with nonvirulent strains of bacilli. Do men ever acquire such immunity? There are reasons for believing that some races, some families, and some individuals have acquired a degree of specific immunity. These reasons are as follows:

1. Most bacillary diseases do produce an individual, and, where they have prevailed for centuries, a certain amount of racial specific immunity.

2. Races heretofore free from tuberculosis, such as the North American Indians, the Eskimos, etc., have shown very great susceptibility once it has been introduced among them. The Indians especially are a hardy, vigorous race. We would expect them to have a high degree of natural immunity. Yet they have proven very susceptible to tuberculosis.

3. Races like the Chinese that have for centuries lived in cities and large communities and have long been subject to tuberculosis, show more resistance than other races.

4. We continually see families without any evidence of great physical vigor, and in which we would not expect much natural immunity, the members of which nevertheless show great resistance.

If these families and races have acquired relative specific immunity it is of course through inherited influence. If there is an inherited specific immunity it is in contradiction to the ideas of past years. Even since we have rejected the teaching of direct inheritance of tuberculosis we have yet clung to the belief that the descendants of an individual having tuberculosis will be predisposed to the disease. It should be remembered that the evidence for this belief is collected from those families in which members have died from the disease. Now inherited specific immunity, if acquired at all, must be acquired in those families that have had and have overcome the disease. We know that unnumbered thousands of every generation in all civilized countries do contract tuberculosis and overcome it, often without having known of its existence. There are of course no records of these generations of recovered cases, and therefore we are not able to show positive evidence one way or the other.

That some of the children of those who have died of the disease should contract it, is of not much weight against the idea of inherited specific immunity. First, they are often subjected to prolonged exposure, and any relative immunity is overcome. Second, such children are often begotten when the parent is in an advanced stage and consequently can but lack in natural vigor.

We referred above to the production of artificial specific immunity in animals by the use of tuberculin, etc. This has already been used successfully in treating incipient tuberculosis. A further use might be made of it in increasing specific resistance in the case of individuals who have been subjected to predisposing influences or directly to the contagion.

Susceptibility.—People are susceptible to a disease if they may be affected by that disease. As applied to tuberculosis it is, like immunity, always relative; at least it is relative so far as the human family is concerned. Some are much more susceptible than others. Those who are extremely susceptible to infection are said to be predisposed.

Predisposition.—This consists in a condition of the bodily cells or juices in which an amount of infective material that leaves other persons unaffected calls forth an attack of the disease in the person predisposed. It is excessive susceptibility. Whatever lowers the resistance of the individual to the bacilli tuberculosis predisposes him to that disease.

There are certain influences and conditions of life, as some occupations, habits, unsanitary homes, other diseases, heredity, etc., that do lower the natural resistance and predispose to phthisis.

Heredity as a Predisposing Influence.—Anything in the environment of an individual that lowers the vitality of his offspring may predispose the offspring to tuberculosis. Among the conditions of the parent that produce an inherited predisposition, chief perhaps, is disease; and among diseases tuberculosis itself is supposed to be of the most importance. That a child begotten by parents weakened by advanced tuberculosis will be predisposed, is conceded by all. That tuberculosis causes a greater predisposition than any other disease inducing a like feebleness in the parent, is not true. There is no "specific predisposition" in the child of the consumptive. As has been pointed out, the occurrence of tuberculosis in children of consumptive parents is due to the opportunity for infection rather than to unusual susceptibility. As suggested in the remarks under inherited immunity, there are reasons for believing that children of parents with an incipient phthisis, more especially of parents recovered from tuberculosis, are not more, but less, susceptible.

Children of very old or of very young parents are usually predisposed to disease. Weakening of the parent by long-continued hardships, by insufficient foods, by excessive sexual indulgence, by alcoholic or other drug intoxication, or by a hundred and one other causes, may act in a like manner.

Of more immediate importance to the family physician are those environments affecting the individ-

ual directly in an adverse manner and producing a personal predisposition.

Crowded and Unsanitary Homes. — We know that this condition is most favorable to the spread of the germs, and this detracts from the weight of this factor in predisposition. Nevertheless, such a condition of life does lower the component cell force of the individual and renders him more susceptible to bacterial invasion; and we believe especially susceptible to infection by the bacilli tuberculosis. Inhabitants of the dark, crowded tenements are pale, weak, and wanting in all forms of vigor. One hesitates to use the comparison of the "prepared soil" so much abused, but it expresses a truth applicable here. The want of sufficient oxygenation prepares the soil for this particular seed. This statement is not supported by observation only. Animal experimentation has proven it true. De Toma, for instance, reports that only animals confined in the dark and insufficiently fed become tuberculous by inhalation.

The work now being done in the large cities to improve tenement houses, while not primarily intended as an antituberculosis movement, will be of great importance in this direction. More light and better ventilation in the houses, frequent playgrounds for the children in the congested districts, will go far to lessen this predisposing factor. The things that predispose to phthisis are often combined. With crowded homes we frequently have also—

Insufficient Food and Food of Poor Quality.— This possibly is of even greater influence in causing consumption than are the dark and ill-ventilated homes. The highest vigor can exist only along with a sufficient amount of good food. Ill-nourished people are susceptible to all sorts of disease. There is evidence that insufficient food directly increases the susceptibility to consumption. From the beginning of the second quarter of the last century, there was great increase in the prosperity of the working classes throughout England. This resulted in better living conditions, and especially in much better foods. The increased consumption of fresh meat was especially noticeable. Now during this period there was a decided decrease in the number of deaths among these very people. This was before the discovery of the specific germ and consequent warfare against its spread. True, there was coincident better housing of the laboring classes. As suggested above, the things that make for and against tuberculosis often occur in groups.

In further support of a poor food supply as a cause of tuberculosis, may be cited the increase of the disease among the negroes of the South since the Civil War. This increase is very marked. Previous to the war the slaves were as a rule well fed by their owners. Since the war they must needs shift for themselves, and for most of them it has been a poor shift. The difference in housing is not nearly so marked as the difference in quality and quantity of food. True, there has been an increase of alcoholic and other drug addictions among them and largely increased irregularity of habits, all of which have had an influence for the worse.

Unsanitary Workshops and Factories. — This heading might well be classed with that of unsanitary homes in so far as the workshop is merely "crowded and illy ventilated." There is a class of factories, however, in which there is much dust and grit, the inhalation of which seems to render the lung tissue vulnerable. Workers in some of the ore mills of our Western country are subjected to this predisposing cause. Those who persist for many years in these mills where the gritty dust must be breathed almost surely contract phthisis. Stonecutters, filecutters, etc., are others of this class.

Age.—Children are more susceptible to most bacterial diseases than are adults. It is probable that the proportion of tuberculosis, taken in all its forms, is greater among children under eight than it is at any other eight years of life's span. The glandular forms are more frequent in children, the pulmonary less frequent than in later years.

Sex.—Excessive child-bearing and prolonged lactation undoubtedly increase susceptibility to consumption. Otherwise sex has no predisposing influence.

Climate.—A cold, damp climate, by causing more indoor life, indirectly predisposes to tuberculosis. Further, such diseases as bronchial catarrh, pneumonia, etc., are more frequent in such a climate, and these diseases increase the susceptibility to consumption.

Disease as a Predisposing Cause.—Any disease that leaves a weakened subject surely has to that extent a predisposing effect. Those diseases that act especially upon the mucous membrane of the bronchial tubes and lungs, together with some other diseases, may have a special predisposing effect. It is difficult to determine positively any such effect, but it seems probable. First, the frequency of such diseases preceding consumption. Second, their effect upon the tissue involved can reasonably be supposed to make it more vulnerable to succeeding infection.

Pleurisy.—This is not a rare precursor of tuberculosis. In some cases the pleurisy may be of tuberculous origin, secondary to a previously existing but undetected tuberculous disease of the lung. There are, however, cases of nontuberculous pleurisy followed by pulmonary tuberculosis. It is difficult to determine whether the pleurisy in such cases is merely the first evidence of a general lack of resisting power to disease, which is further evidenced by the tuberculosis, or whether the often resulting partial immobility of the lung specially predisposes to phthisis.

Diseases of the Heart. — Many years ago Dr. Brehmer called attention to the relationship between a small, weak heart and the development of consumption. He believed that a heart small in proportion to the lungs was one of the chief causes of the disease. This was before the discovery of the *Bacillus tuberculosis.* It seems reasonable, in the light of the bacillary origin, that a heart not capable of keeping up a vigorous pulmonary circulation might well be a predisposing cause to the infection of that lung. Certain it is that many consumptives have small and weak hearts. Families in which phthisis is frequent often show this characteristic. It is well known that many athletes succumbed to the disease. The excessive exertion often results in distention of the heart, with resulting weakness of that organ. I think it may be definitely stated that a weak heart is one of the chief predisposing causes of phthisis.

Diabetes. — This disease is generally associated with diminished activity of the heart, and of all constitutional diseases is first in predisposing to tuberculosis. It is well known that sugar added to the culture media produces a more abundant growth of bacilli. It is possible that the sugar in the system

of the diabetic plays its part in making him more susceptible.

Worry and Grief.—The number of patients who date their disease to a time of especial grief or of excessive worry is noticeable. It has seemed to me, however, that the breakdown of the patient usually comes too close to the time of stress to feel that it is the cause of the tuberculosis. Rather it has seemed that the tuberculosis already existed and the worry or grief has been the immediate cause of its activity. However, anything that may cause the sudden activity of an existing tuberculosis would presumably predispose to the first infection.

Excessive Use of Alcohol.—The habitual use of even moderately large amounts of alcoholic liquors undoubtedly predisposes to tuberculosis. We base this statement upon the physiological effect of alcohol. H. C. Wood says: "In large amounts it is certainly depressant to the cerebral and spinal ganglionic cells, as well as to the nerve trunks; it depresses the respiratory centers; upon the heart it acts as a depressant or paralysant; it disturbs all nutritive processes." All these actions of alcohol make for susceptibility to disease. That *excessive* use of the drug tends to predispose, is a matter of common observation. In the case of habitual drunkards we have not only the direct effect of alcohol upon the system, but also, in most cases, the resulting exposure, insufficient food, and often other excesses added to the effects of the alcohol. Societies for the prevention of the spread of tuberculosis would do well to add teetotal principles to their platform.

This has not been an attempt to write of everything that could possibly increase the susceptibility of the individual to phthisis, but only of the more active and more common. Would it not be well to add a discussion of these things to the literature prepared for the laity, teaching how to prevent the spread of tuberculosis? At present this literature is confined to the discussion of measures aimed to prevent the spread of the specific germ. To lessen the vulnerability of the individual is a close second in importance, if second.

Another point of practical worth regarding the factors that predispose to phthisis, is the application in the treatment. Chronic tuberculosis is a disease of alternating advance and quiescence. By keeping the patient in the "straight and narrow path" of healthful living, we can in most cases avoid the lighting up of the quiescent tuberculosis. We need to be alert to see that nothing is done that makes against the best possible health. Those things that predispose to the first infection will also tend to further infection and to activity of the focus already existing.

TUBERCULOUS PERITONITIS.*

By JOHN B. BOUCHER, M.D.

HARTFORD, CONN

SURGEON TO ST. FRANCIS HOSPITAL.

Tuberculous peritonitis is dependent upon an infection by means of the bacilli circulating in the blood, or upon an extension of tuberculous inflammation, or ulceration from adjacent organs. All agree that the tubercle bacilli are the invariable cause of the disease, but the source of invasion admits of more and various opinions; the route by which they reach the peritoneum is frequently difficult or impossible to determine, but is evidently by many different sources. Dieulafoy believes that the most frequent source is through the intestines, where the bacilli have been introduced by sputum or food, infected milk, or meat. Clinically I do not believe that we can eliminate bovine tuberculosis as a source of infection in man. The work of Salmon, Ernst, and a host of other accurate observers has shown the possibility of infection through the milk and food supply. The structure of the large follicles of the intestines and of Peyer's patches corresponds closely to the follicles of the tonsils. We know that next to the lungs the most susceptible localities to tuberculous invasion are the tonsils, where the lymphatic tissue lies directly exposed on the mucous surface; in the intestines and appendix practically the same condition exists. The bacilli may attack the intestines primarily and the peritoneum next, or being absorbed by the superficial lymphatics of these structures, may attack the peritoneum first; this hypothesis is confirmed by the experience of Wesner and Cornil. Unquestionably the bacilli are capable of passing through the walls of the intestines without a primary lesion of the bowel, and thus reaching the peritoneum without leaving any trace of trouble at the atrium of invasion, as it so often does in the pharynx when the cervical glands become infected. Primary tuberculosis of the intestines occurs in three forms: (1) Multiple ulcers, due to inoculation from sputum; (2) single ulcerations, especially in the ileum, which have a marked tendency to heal with stricture formation; such cases are usually seen with obstruction; (3) conglomerate tuberculosis, usually at the ileocecal junction, giving rise to a tumor and having the gross appearance of carcinoma; the last two forms are usually primary and are due to accidental inoculation. We can best study inoculation tuberculosis in the surface infections, such as the finger of the demonstrator of anatomy, or the infection so often occurring in students in the dissecting room; here, regional lymphatic invasion usually occurs, with a tendency to remain local, and the tubercle bacilli may be demonstrated in the glandular involvement.

We will consider a most fruitful source of tuberculous peritonitis, and it is not impossible that this is the most frequent source of infection, namely, through the Fallopian tubes in woman. Abdominal surgeons have taught us that the disease occurs more commonly in females than males, owing to the fact that the Fallopian tubes are a favorite seat for primary tuberculous infection. They seem to have a special affinity for the tubercle bacilli, in this respect nearly resembling the alveoli of the lungs. The Mayos found localized tuberculosis of the intestines about equal in males and females, while they found tuberculous peritonitis four times as frequent in women. In the last sixteen cases reported, they found eleven in women, in nine of whom the origin of infection was in tuberculous tubes; one in the appendix, one unlocated; five were in men, three with tuberculosis of the appendix and cecum, two unlocated. In this series of cases over 56 per cent. were produced by tuberculous tubes. As Hegar pointed out some years ago, the tubes are predisposed to tuberculosis by their spiral form and pleated mucosa, which favor stagnation of secretion. A preliminary catarrh seems to enhance the danger of infection, the sources of invasion being numerous, such as ascending infection, either through the blood or lymph vessels. It is possible that tubercle bacilli finding their way to the peritoneal cavity from any source at once attack this favorable soil. Pinner's experiments show that fine particles of lampblack introduced into the abdominal cavity find their way

*Read before the State Medical Society at New Haven, May 24, 1906.

through the tubes into the uterus; likewise that tubercle bacilli are capable of migrating through the walls of the Fallopian tubes as well as through or from its fimbriated ends. The normal constriction and valves of the tubes, about five-eighths of an inch from the uterus, favors the arrest of the bacilli at this point. Clinically this is the most frequent area involved, and the pathological changes indicate that the primary focus is in the tubes. It is also at this point that the gonococcus infection is arrested and retained sufficiently long to destroy the mucosa and produce the stricture which is the most prominent etiological factor of gonorrheal pyosalpinx. In the male we may have a migration from the seminal vesicles, the epididymis, the vessels of the spermatic plexus through the ampullar ends of the vas deferans, and the lymph vessels of the latter.

It must be borne in mind that we may have extensive disease of the peritoneum without involvement of the tubes. Other sources are the blood current, the lymph current, especially from the mesenteric glands, the pleura, and genitourinary tract. As a rule it may be stated that the most common source of infection in males is, first, the intestinal tract, next the genitourinary tract; and in females, the genital tract, especially the tubes.

Any previous condition which tends to weaken the resistance of the peritoneum will act as a predisposing cause; for example, acute peritonitis, pelvic hematocele, enteric fever, and especially the puerperium. Kelly believes that the influence of parturition has not been sufficiently recognized. In this connection we must also keep in mind the fact that as a rule it requires either an inherited or acquired tendency to the disease. The peritoneum is greatly exposed to the danger of tuberculous infection. Tuberculosis as a rule attacks this membrane in one of two types; in the one it is accompanied by a widespread formation of free connective tissue, with multiple adhesions between the various viscera; in the other it is associated with profuse exudative processes. Very frequently the disease starts with the perforation of a caseous mesenteric or retroperitoneal gland, the process becoming diffused by means of the peristaltic activity of the intestines, or localized, if adhesions have previously been formed. In the same fashion tuberculous ulceration of the intestines may give rise to disease of the peritoneum, especially the slowly perforating type of ulcers. In case of sudden perforation, a rapidly fatal peritonitis is set up by the pathogenical microorganisms which escape into the peritoneal cavity. Genital tuberculosis, especially in women, is very frequently the point of departure for a peritoneal tuberculosis. The bacilli are especially apt to find their way out of foci situated in the distal extremity of the tubes unless the peritoneum has been previously walled off by the formation of a false membrane. The organisms find their way either through a free opening or through the lymph spaces in the mucous membrane, notwithstanding the opposing action of the ciliated epithelium of the tubes. The tuberculous process may be transmitted from one serous membrane to another: for example, from the pleura to the pericardium and the peritoneum, or vice versa. In the case of rupture of a tuberculous focus into the blood stream, the serous membrane may participate in the general disease, with the formation of multiple miliary tubercles.

Age is an important factor. During the period from fifteen to forty, corresponding with the menstrual activity in women, it is most frequent, although it is not uncommon in children under ten years of age. After the age of menstrual activity it rapidly decreases in frequency. In America, negroes are more prone to the disease than white people. The symptoms vary considerably in certain special features from other forms of peritonitis. It presents a symptom complex of extraordinary diversity. The process may be latent and not cause a single symptom. Such cases are met with accidentally in operating for other conditions. In other cases the onset is so sudden and the symptoms so pronounced that erroneous diagnosis of enteritis or strangulated hernia may be made. Instances are recorded where the operation for strangulated hernia has been performed. Many cases are ushered in with the symptoms of acute peritonitis and abdominal tenderness. Other cases resemble typhoid fever very closely, and may lead to error in diagnosis; ascites is frequent, but the effusion is rarely large and may sometimes be hemorrhagic. In this form the disease must be differentiated from acute miliary cancer, cirrhosis of the liver, and chronic simple peritonitis. It must not be forgotten that tuberculous peritonitis may be secondary to cirrhosis of the liver in a considerable percentage of cases. Tympanites may be present in very acute cases, when it is due to loss of tone in the intestines, owing to inflammatory infiltration, or it may occur in old, long-standing cases where universal adhesion has taken place between the parietal and visceral layers. Fever is a marked symptom; in acute cases the temperature may reach 103° or 104° F. In the more chronic cases subnormal temperature is common, and for days may not rise above 97° F.; the morning record may even be as low as 95.5° F. Occasionally pigmentation of the skin is present and has in some cases led to confusion with Addison's disease (Osler).

A striking peculiarity of tuberculous peritonitis is the frequency with which either the condition simulates or is associated with tumor, and this may be: (a) Omental, due to puckering and rolling of this membrane until it forms an elongated, firm mass attached to the transverse colon and lying across the upper part of the abdomen. This cordlike structure may also be found with cancerous peritonitis, but is much more common in tuberculosis. A resonant percussion note may sometimes be elicited above the mass. Though the tumor is usually situated at the umbilicus, it may be present in the right iliac region. (b) Sacculated exudation, in which the effusion is limited and confined by adhesions between the coils, the parietal peritoneum, mesentery, abdominal, or pelvic organs. The encysted exudate is most common in the middle zone, and has frequently been mistaken for ovarian tumor. It may lie completely within the pelvis, associated with tuberculous diseases of the Fallopian tubes. (c) In rare cases the tumor formation may be due to great retraction or thickening of the intestinal coils. The small intestine is found shortened, the walls enormously thickened, and the entire coil may form a firm knot close to the spine, giving on examination the idea of a solid mass. Even the entire bowel from the duodenum to the rectum has been found forming such a hard, nodular tumor. A case has recently occurred in the writer's experience in which it was found that the entire intestinal tract was contracted to a fibrous cord in which the lumen of the bowel would scarcely admit a small lead pencil, the walls being greatly thickened.

The diagnosis of these peritoneal tumors is sometimes very difficult. The omental mass is a less frequent source of error than any other, but a similar condition may occur in cancer. The most important problem is the differential diagnosis of saccular

exudation from ovarian tumor. In fully one-third of the recorded cases of laparotomy in tuberculous peritonitis, the diagnosis of cystic ovarian disease has been made. The most suggestive points for consideration are the history of the patient and the evidence of old tuberculous lesions. The physical condition is not of much importance, as in many instances the patients have been robust and well nourished. In the diagnosis, the association of tuberculous conditions of the other organs should be carefully considered.

The surgical treatment of tuberculosis of the peritoneum involves the following propositions: (1) To remove or shut off the source of supply to the peritoneum of new tuberculous débris. (2) To remove the products of the infective process from the peritoneum. (3) To remove the tissue proliferation for the encapsulation of the foci already present; and (4) to avoid mixed infection (Murphy). Too early intervention is unwise, since the tuberculous process may be still in a period of evolution. The tendency of surgeons at the present time is to operate after the pain and discomfort from the ascites and adhesions have become so marked that relief is imperative. The first surgical work for tuberculous peritonitis dates back to 1862, when Spencer Wells performed a laparotomy for supposed ovarian cyst and found to his astonishment that the patient was cured. Laparotomy was advised as a therapeutic measure by König in 1884; during the next fifteen years simple laparotomy with evacuation of fluid and closure of the wound gave a large percentage of recoveries, various surgeons reporting from 50 to 75 per cent. of cures from simple laparotomy. Various theories have been advanced as to how the process of recovery is brought about. Veit claims that by evacuating the effused fluid suddenly and completely, a new effusion of normal serum occurs immediately, which is possessed of bactericidal power in the highest degree, hence the struggle against the microbes will have the best chance of succeeding; if, however, fresh bacilli continue to penetrate into the peritoneum, or a tuberculous focus elsewhere in the body partly neutralizes this antitoxic power of the serum, healing cannot result. In contradistinction to this theory, Murphy believes that effusion of new serum following laparotomy does not possess antitoxic properties which destroy the bacilli; on the contrary, it possesses equal or greater toxicity than the original serum; the curative properties are brought about by inflammatory reaction and the most active cell proliferation; it is this tissue proliferation which overwhelms and encapsulates the tuberculous foci on the surface of the peritoneum.

Personally, I believe that simple laparotomy, with removal of the fluid, acts in two ways, first, that in tubal disease the fluid mechanically separates the fimbriated extremity of the tubes from the surrounding tissue; second, after removal of the fluid, contact with neighboring structures with resultant adhesions may follow; this prevents peritoneal reinfection and confines the product to the pelvis. It also accounts for the lateral pelvic masses which are sometimes developed after the disappearance of the fluid. It also enables nature to bring her resources to bear on a localized focus and develops the self cure that has been noted in so many cases. The operative manipulation causes the serum to be poured out, and thereby increases the peritoneal power of absorption (Mayo).

To Murphy and the Mayos belongs the credit of demonstrating that in a large percentage of cases of tuberculous peritonitis with ascites, the foci of infection are in the Fallopian tubes and appendix. Acting upon the knowledge thus acquired, they have in their later cases removed the tuberculous tubes and appendix when so found, with the result that they have cured a large percentage of cases that were formerly only temporarily benefited by simple laparotomy. Mayo says, "Of the twenty-six radical tubal operations we have performed on cases of tuberculous peritonitis, twenty-five recovered; of these, seven had been operated upon by simple laparotomy from one to four times previously. In not a single instance as yet has another operation become necessary, and as contrasted clinically with the preceding group of equal numbers, the favorable results are most striking. There is usually a temporary continuance of the peritoneal effusion, but reinfection has not occurred." The outcome where the appendix has been the seat of the trouble has been favorable, but not so brilliant as in the tubal form of the disease.

The percentage of recoveries in tuberculous peritonitis from operative measures must depend largely upon our classification of cases. The surgery of the disseminated serous variety, which in the great majority of cases is associated with, or due to tuberculosis of the tubes, gives us the most brilliant results, while in the dry and ulcerative forms of the disease it is followed by high mortality and little is accomplished by surgery. In the inflammatory, localized suppurative form, the operative outcome is quite favorable, while in the suppurative multilocular cystic variety but few recover.

A word in regard to the technique of operation. Under thorough antiseptic precautions the fluid is evacuated and the general abdominal cavity is packed off in the usual manner. The pelvic organs, appendix, and cecum are examined. If the Fallopian tubes, appendix, and cecum are diseased, they are removed, the stumps and walls of tuberculous abscess cavities are dried, and a little sterile iodoform rubbed in and the abdomen closed. In extensive tuberculosis of the bowels, with widespread adhesions, resection is a hazardous procedure, and is usually a futile undertaking. It is often followed by fecal fistula when the patient survives the operation. In such cases the infected area should be excluded from the fecal current by short-circuiting the intestines. The tuberculous process in the excluded portion ceases to advance and often heals, the patient's life may be prolonged and he may be relieved of most of his disagreeable symptoms.

From the facts already stated, I think we are justified in believing that failure of simple laparotomy with evacuation of the fluid exudate in tuberculous peritonitis, to maintain its proper standing in surgery is due to reinfection from lesions in the mucous membrane of the organs enumerated. We have been treating a symptom instead of removing a source of disease. It is true that at times the lesion cannot be discovered, but it is equally true that radical operation on the primary lesion in tuberculous peritonitis will greatly increase the percentage of cures and prevent reinfection of the peritoneum.

In conclusion, we are forced to believe that tuberculous peritonitis, like septic peritonitis, has its origin in a local focus in nearly every case. Peritoneal reinfection may be prevented if we are successful in removing the local focus. Whether the patient will remain cured must depend upon whether the local focus thus removed is primary or secondary; if primary, we can hope for good results, but if secondary, it must depend upon the possibility of cure of the primary seat of the disease.

AN URGENT PLEA FOR THE USE OF LARGER DOSES OF ANTITETANIC SERUM FOR LOCKJAW, WITH A CASE IN POINT.

By ROSA ENGELMANN, M.D.,

CHICAGO.

ECTOR CHICAGO HEALTH DEPARTMENT; ASSISTANT CLINICAL PROFESSOR PEDIATRICS (EXTRA MURAL), RUSH MEDICAL COLLEGE.

In view of the yearly Fourth of July fatalities and the high mortality rate of tetanus, the history of the following case may be opportune and instructive. Furthermore, because of an eleven years' connection with the Health Department as an antitoxin administrator, I have been impressed with the fact that the general practitioner does not give large enough doses of this life-saving remedy for diphtheria. Again, surgeons as a rule question the utility of antitetanic serum. Even J. B. Murphy, after giving three full doses, says that "treatment by antitetanic serum is unavailing." He does not state, however, the amount of his full doses.

When, therefore, a case of tetanus occurred in the line of some industrial institutional work that I was doing, I drew a parallel inference with respect to the antitetanic serum and proceeded to administer the latter by both intraspinal and subcutaneous injections to the amount of from 60 c.c. to 80 c.c. daily to begin with—a total of 650 c.c., of which 520 c.c. was given subcutaneously and 85 c.c. subdurally and 45 c.c. directly into the wound. I reasoned that if the poison traveled from the latter along the nerves, perhaps the antitoxin would take the same route and thus limit the disease process. This injection was so painful that I did not give it more than twice. After five days of this treatment the man was comfortable, with flaccid muscles and less rigid jaw. Upon stopping the use of the serum greater trismus and general muscular rigidity and spasm ensued. He also complained of what he called contractions of the back and legs.

Dr. Arthur Price, who saw the case with me, discouraged the use of serum, saying that in his and other surgeons' experience at Cook County Hospital it had proved useless. I claimed that its ineffectiveness was probably due to inefficient doses, and proposed to use it in large amounts both by subcutaneous injection and spinal puncture. In two days I proved to the satisfaction of Drs. Price and Hayden that the man not alone had not grown worse, but that there was even slight improvement.

The man was so rigid and we were in such fear of inducing convulsions that he was not raised when the spinal punctures were made and no cerebrospinal fluid escaped. Despite these daily intraspinal injections of 20 c.c. no cerebral pressure symptoms occurred. There was, however, a slight rise of temperature and pain was felt in the neck and head after each cervical spinal injection. After giving a few such, at the suggestion of Drs. Price and Hayden I employed lumbar punctures only. Subcutaneous injections were also given daily almost continuously up to the third week. It was remarkable with what ease the spinal canal was entered and how little pain the injection gave the patient.

Chloroform was given at the first puncture only, and with the view of producing jaw and general muscular relaxation. A few whiffs had likewise been given during the first convulsion that occurred while I opened up the wound that from a recurrent painfulness, redness, and swelling, seemed to be the seat of the tetanic poisoning. This was not the original punctured wound between the dorsal heads of the second and third metacarpal bones, but a counteropening made for drainage in which one catgut suture had been placed. This catgut had not absorbed properly in other wounds from which I later removed it in several instances, but as I had no other at hand, I was obliged to use some from this same lot for a spouting vessel. I am inclined to believe, although I cannot prove it, that this catgut was the cause of the tetanus that occurred nine days after this man's discharge from the hospital with both wounds healed.

Before proceeding to the detailed history of the case I also wish to give Drs. Hayden and Harvey E. Mock credit for their careful examinations, care, and records supplementary to this successful issue.

I also wish to add that for five days chloral and bromides were given in daily decreasing doses, and elimination was secured by colonic flushings, laxatives, baths, and massage.

I realize that this was one of the subacute or chronic cases of probably long incubation period, of which, according to V. Schuchman, 47 per cent. recover without serum and 80 per cent. with serum administration. But I cannot believe that a complete recovery could have taken place in so short a time as four weeks, and that at the end of six weeks the man could have been back at work trucking.

He suffered severely from serum erythema and muscular and joint pains. Two months after his recovery from tetanus, he is suffering from the first subacute attack of rheumatism that he has ever had. Probably he has been made susceptible by the attack of lockjaw, the use of such large amounts of antitetanic serum, or both. Welcome will be the day when serum can be largely separated from the antitoxin, so that the deleterious serum effects will be eliminated.

E. B., 45 years old, muscular man, trucker. No venereal or alcoholic history. There was a small punctured wound in the dorsum of the left hand at the interspace between the heads of the first and second metacarpal bones. This was freely opened up and a subsequent lymphangitis and cellulitis received surgical attention for thirty-eight days, when he was discharged cured. The Bier suction or passive congestion method supplemented our surgical treatment, and materially hastened granulation of the wound as well as reduced the swelling and redness of the forearm. Not having the regular Bier apparatus at hand, we devised one, namely, using a bicycle pump, a large glass irrigator, a rubber glove, and some rubber tubing for this purpose. Nine days after discharge he returned with swelling and redness of the same hand and entire arm, with tenderness over the counterincision that had been made some weeks previously. I opened up the latter again, packed same with iodoform gauze, and applied large hot alcohol dressings. While doing this he had a typical tetanic convulsion on the table. Before and after this he suffered from pronounced trismus, risus sardonicus, opisthotonos, and such general muscular spasm that there was no question as to the diagnosis. He had had fearful pain and cramps in his back and legs for three nights, so severe that he walked the floor.

We placed the man in a dark, quiet room, with night and day nurses. His jaw was firmly locked, leaving a fourth of an inch aperture only. He was suffering from opisthotonos, general muscular rigidity and spasm, and showed all the signs and symptoms of tetanus. He remained in the hospital for one month, when we discharged him, well, sending him for a two-weeks' trip to the country for absolute recuperation. At the end of six weeks he returned to work as a trucker.

He received daily colonic flushings and sponge baths. For five days he received ten grains of chloral hydrate and 30 of sodium bromide. For the first two days, at four-hour intervals, for the third and fourth days at 4 P.M. and 8 P.M., and finally but once a day. He took liquid nourishment well, and no other until the eighth day, when he was able to take mashed potato and milk toast with a poached egg. Soft foods were continued for four or five days longer, when upon the fifteenth day he was able to chew beefsteak. From thence on he was regularly on a solid diet. There was a leucocytosis on the first day of 13,150, and, upon his discharge, of 9,450; hemoglobin, 80 per cent. The first count was made within six hours after the injection of the antitetanic serum; the second count was made eighteen hours after the injection of the same; another count was made on April 16: hemoglobin, 80 per cent., white corpuscles, 18,600.

The urine was examined four days after his entrance: Color, dark red; reaction, acid; specific gravity, 1,028; albumin, none; sugar, none; amorphous phosphates and sediment and cells.

For the first five days his temperature ranged from 98° to 99°; his respiration was from 20 to 24 to 36, and his pulse ranged from 78, 82, and as low as 76.

On April 11 at 2 P.M. I injected 10 c.c. of antitetanic serum by lumbar puncture. At 4 P.M. a subcutaneous injection of 20 c.c. of antitetanic serum was made. On April 12, in addition to the subdural administration, I injected 15 c.c. directly into the wound. I did this instead of opening up the brachial plexus and injecting into it, reasoning that since the poison traveled through the radial and ulnar nerves into the brachial nerve the antipoison or antitetanic serum would travel the same course through the brachial plexus.

The last injection of 20 c.c. was given on April 25. From that time there was continued improvement until May 2, when we sent him out-of-doors, where he remained most of the day during pleasant weather until his discharge. He complained of so much pain and stiffness in the ankles and walked with such difficulty that we gave hot footbaths and massage. There was pronounced tenderness along the brachial nerve, and much pain in the forearm, arm, and shoulder for some weeks.

On May 13 he was discharged from the hospital and sent to the country.

Before leaving Dr. Harvey E. Mock made an examination of the reflexes, which were found to be as follows: Patellar reflex of left leg was normal; patellar of right leg was greatly exaggerated; it was this leg that had given him the greatest trouble. Elbow reflexes normal. The plantar cutaneous reflexes were normal; Babinski negative in both feet; cremasteric normal although not marked; abdominal reflexes were normal. There was pupillary reaction to both accommodation and light. Taste was normal. There was a small area on left side of the face just in front of the ear, about one inch square, where there was complete loss of pain sense and delayed touch sense. The upper border of the zygoma formed the upper border of this area and it extended over a distance of one inch in front of the left ear.

May 15.—Still walked stiffly from pain in ankles (spastic gait) and complained also of pain and stiffness of left arm. Could not flex forearm upon arm. Tenderness upon pressure of brachial and ulnar nerves. Slight pain but no stiffness of left masseter muscle.

May 25.—All these signs had disappeared, except nerve tenderness.

June 1.—Appeared and felt perfectly well. Had been for two weeks in the country where he regained lost flesh. Returned to work as trucker six weeks after the onset of the disease.

DIPSOMANIA.*

By CHARLES J. DOUGLAS, M.D.,

BOSTON, MASS.

MEDICAL DIRECTOR OF DR. DOUGLAS' SANATORIUM

In the discussion of obscure pathological conditions, especially of those relating to the nervous system, clear definitions are of great importance. Dipsomania is one of those ailments that is sadly in need of a definition that will not only state what it is, but also what it is not, and will clearly mark out its boundaries. Where shall we run the line of demarcation between the mere habit of drinking and the disease of dipsomania? This disease clearly affects the nervous system and is often as uncontrollable as epilepsy, and yet every man who occasionally drinks wine with his dinner is not a victim of the disease, although he is looking in that general direction, and may get there in time. We cannot define it as a state of alcoholic intoxication, for many men are constant sufferers from some of the symptoms of dipsomania who are sober most of the time. The craving may be there, although resisted for a time or temporarily obliterated. Nor can we say that it is a craving for liquor as a palatable beverage, for distilled liquors are almost universally obnoxious to the taste of drinking men. Neither is it a weakness of the will nor of morals nor of intellect, for men of unusual strength in all of these particulars are often victims of this disease. Nor is it essentially a disease of the stomach or liver or kidneys, although any one or all of these organs may be involved. With these limitations in view, I will venture to suggest the following as a definition of dipsomania:

An abnormal demand of the nervous system, either constant or periodic, for the drug action of alcohol—a demand so strong that the patient takes the alcohol in spite of his earnest wish and effort to avoid it.

The last clause of this definition is an important one. If a patient can voluntarily abstain from the use of alcohol one year, he has either been cured of dipsomania, or he never had it. The mere habit of drinking alcohol, like the habit of drinking milk, can be abandoned at any time without any serious effort of the will. But dipsomania, the disease, makes the strongest wills bend to its behests.

It is a curious fact that most alcoholics deny having a "craving" for alcoholic beverages. "The abnormal demand of the nervous system for the drug action of alcohol is so subtle and deceptive in its nature that its victims do not recognize it, and are themselves mystified as to why they drink when they have resolved not to, and were so sure they would not. A man whose word is as good as his bond will promise in the morning that he will not take a drink that day. Perhaps he never made a promise more seriously, and felt absolutely sure that he would keep it. But by night he is intoxicated. After he has come to himself ask him why he did it and you will find that he is unable to give a reasonable explanation. As a rational human being he may feel that it is incumbent upon him to give some excuse for his

* Read before the American Medical Society for the Study of Alcohol and Narcotics, at Boston, June 6, 1906.

conduct, and he may reply to your question by saying that the weather was cold, or it was hot, or he met a friend, or he didn't meet a friend whom he expected, or some other equally foolish excuse. But in point of fact the man had, without knowing it, a good and valid reason for getting drunk that day, and that reason is that he is a diseased man. There is a pathological condition of the nervous system that caused an abnormal demand for alcohol. He may be perfectly sound in every other particular, but in this one he is an invalid. He thinks he has no "craving" for liquor, but somehow he gets drunk, notwithstanding his wish not to. An example will illustrate this peculiar phase of our subject:

Several years ago a gentleman of high character and wealth came to my sanatorium to consult me regarding himself. He said, "I drink to excess, and it is abhorrent to me, and I would gladly do anything to stop it. But I fail to see what a physician can do in my case, for I have no 'craving' to be cured." I asked him to state the circumstances of his drinking, and he replied that frequently he would have a restless feeling evenings and a desire to mingle with his friends, and consequently would go to the club for a chat with his business acquaintances. He had no conscious thought of drink. But after reaching the club drinks were naturally proposed, and in his case intoxication resulted. I then asked him if, when he had this restless feeling, he ever sought the society of friends who did not drink. After a moment's pause he said, "I never thought of it before, but I believe I never do." He was really seeking drink when he thought he was craving for the society of his friends. A clear case of dipsomania. The abnormal demand for alcohol was there, but he did not recognize it. He stayed with me under sanatorium treatment several weeks, and has been a total abstainer ever since.

Broadly speaking, the boundary line between the habit of drinking and the disease of dipsomania is passed when the patient has ceased to be able to abstain any length of time at will, and has reached the point where he drinks regardless of his earnest desire and effort to abstain. But the patient seldom realizes when this line is passed.

Previous to the nineteenth century inebriety was generally regarded as a crime to be punished, rather than as a disease to be cured. Our own great Dr. Benjamin Rush, whose breadth of wisdom has illumined so many subjects, was one of the first to call the attention of the medical profession to the fact that inebriety is a disease. As formerly the insane were merely chained as a menace to society, without much attention to rational treatment or humane nursing, so the alcoholic has been classified as a criminal rather than as an invalid. But it has now become well established in medical circles that dipsomania is a disease, and as such is entitled to medical care. This view was well stated many years ago by that eminent physician, Dr. Valentine Mott. He said: "In my professional life of over forty years I have accumulated facts enough to prove beyond all doubt that inebriety is a disease, affecting every membrane, tissue, and nerve of the human mechanism, producing in its victim a compound fracture from the crown of his head to the sole of his foot, as well as a mental and moral dislocation."

The first institution in the world for the medical treatment of alcoholism was built by the State of New York at Binghamton, in 1858. It was established as the result of a petition to the Legislature signed by over a thousand physicians, under the leadership of Dr. J. Edward Turner. To the zeal and intelligence of this one physician is due the credit for this initial establishment. The ceremony of laying the cornerstone was conducted by a group of brilliant and distinguished men, and letters were received from the President of the United States and members of his cabinet. Edward Everett, then at the zenith of his fame, delivered the principal address, in which he declared, with true prophetic vision, that the work there begun would be taken up by other communities, until the principles there established would be utilized as a blessing to all mankind. This prediction has proved correct. As early as 1863 Gov. Andrew, in his address to the Legislature, said: "Drunkenness is a disease as well as a sin. We have long since legislated for its punishment; let us no longer neglect to provide for its cure. By every motive of humanity and reason, by every law of duty, it challenges our consideration."

A few years later a joint special committee of the Massachusetts Legislature brought in a report in favor of the medical treatment of alcoholism, in which they say: "We know these patients cannot be successfully treated at home; they ought not to be associated with criminals nor with the insane; neither should they be neglected."

In 1870 the late Dr. N. S. Davis, one of our most distinguished American physicians, said in a published address: "If the inebriate is the victim of a positive disease induced by the action of an alluring and deceptive physical agent, alcohol, will any number of moral lessons addressed to his intellect, or any amount of denunciation hurled at his degradation and his vices, cure or reform him? Or will his arrest, arraignment in a police court, and extortion of the few dollars he has left, as a fine, eradicate the disease that is preying upon the most delicate parts of his organization? Abundant experience through the civilized world answers these questions in the negative. The treatment demanded by the nature of inebriation and the interest of humanity is the same in kind as that awarded to the sick and insane."

The seed sown by these and many other eminent physicians is now bearing a beneficent harvest. Their contention that dipsomania is a pathological condition, and a curable one, is now generally accepted, and many private sanatoria are now established throughout the country, where this disease is being scientifically treated and cured. I do not, of course, here refer to those widely advertised concerns, wholly owned and controlled by laymen, whose secret nostrums are dispensed in a routine way by some accommodating doctor who is hired to come in and give a semi-professional appearance to the institution. These so-called "cures" that flourished over a decade ago have been rapidly disappearing. No self-respecting physician can countenance such enterprises. But I have reference to those ethically conducted sanatoria where alcoholism is carefully studied and treated by men who make a specialty of such ailments, and where no unprofessional methods will be tolerated. These sanatoria are increasing in numbers and efficiency, and are doing a great work in this important field.

Dipsomania partakes of the nature of both a neurosis and a psychosis, the predisposing cause being a nervous system that is peculiarly susceptible to the poisonous or intoxicating action of alcohol. Two brothers brought up in the same intellectual and moral atmosphere begin their careers as moderate drinkers. One of them may become a drunkard, while the other does not, because alcohol is more poisonous to the one than to the other. Possibly the brighter man of the two, the one with the stronger will and the more forceful intellect, is the one to become the victim of alcoholism. Watches are more

easily damaged than stone-crushers, and a man who has a fine-grained and highly-developed brain and nervous system is more liable to be injured by alcoholic beverages than one who is less highly organized. There are few people who want to be drunkards. Most drinkers would gladly make great exertions to avoid that fate, and when they reach that dilemma they try all sorts of expedients to extricate themselves. They "swear off," or sign the pledge, but usually without avail. Asking a man who is subject to a physical malady to pledge himself not to have another attack is manifestly an unsatisfactory method of treatment. The pledge method may prevent people from acquiring the disease, but after it is acquired other methods are more successful. I think we may safely lay down the following as a fair statement of the underlying etiological principle:

Dipsomania is not a mere "habit," but is a curable disease which is developed in drinking men, not as a result of weakness of will, or of intellect, or of morals, but because of a peculiar susceptibility of some nervous systems to the poisonous action of alcohol.

Dipsomania can be cured. This proposition is abundantly proven by the testimony of thousands throughout this and other countries. It cannot, however, be properly treated at home. The patient should be removed from his customary surroundings and should devote his entire time and attention to the business of getting cured.

The question as to what constitutes a cure of this disease has often been debated. Some have held that if an habitual drinker remained a total abstainer and free from the alcohol crave for one year after treatment he should be set down as cured; while others have contended that if he ever drank again he had never been cured. The latter position is manifestly absurd, for according to that a patient could not be classified as cured till after he was dead!

A great variety of remedies will be indicated at different times. Each patient must be studied and his abnormal peculiarities noted, and every means known to medicine should be available in restoring him to a normal condition. In addition to many remedies from the Materia Medica, electricity, mechanical vibration, baths, etc., will at times be found to be valuable methods of treatment. In some conditions of the nervous system I have employed the high frequency current with most excellent results. The nerves should receive especial attention, for dipsomnia *per se* is a disease of the nervous system. Other organs frequently are involved, and should be properly treated, but these complications are not essential accompaniments to dipsomania.

In most cases I administer some remedies hypodermically, and have stated hours for doing so. This method has a number of advantages. It brings the physician and patient face to face with each other at regular intervals, thus enabling the physician to note clearly the progress of the case. Remedies thus administered act more promptly. Their action is more uniform and sure, as they do not go through the process of digestion but enter directly into the circulation. This method is available when medicines are rejected by the stomach. My method of using the needle should more properly be called intramuscular rather than subcutaneous, as I insert the needle perpendicularly into the body of the muscle. If skillfully done, this method is painless and, in my experience, has never produced an abscess.

I usually prescribe alcoholic liquors during the first few days of treatment, as I find the "gradual withdrawal" plan the most satisfactory one. This is especially important in delirium tremens. In this condition the three most important indications are: (1) moderate alcoholic stimulation; (2) nutrition, and (3) sleep. Delirium is apt to occur after a spree when alcohol is suddenly withdrawn, and in most of these cases the patients have had less than the normal supply of nutrition and sleep. For nutriment milk and raw eggs are perhaps the best if the stomach will retain them. If these are rejected, hot malted milk will often be tolerated. For a hypnotic, apomorphine, gr. 1-30 hypodermically administered is the most prompt and effective drug. I first published my discovery of the hypnotic action of apomorphine several years ago, previous to which time it was supposed to contain no hypnotic properties. Since then the standard text-books have described my method of employing this remedy, usually giving me credit for its discovery. (See *New York Medical Journal,* October 28, 1899, and March 17 and November 17, 1900; also *Merck's Archives* for June, 1900.)

Dipsomania is a disease that has cursed mankind through all the ages of recorded history. It is to-day one of the most widespread and disastrous of all chronic diseases, and yet for a malady so common and so curable it has been strangely neglected by the medical profession. In my judgment it deserves and will yet receive the earnest and diligent study of our ablest practitioners.

Cause of Rupture in Tubal Pregnancy.—Romolo Costa advances the hypothesis that hemorrhage, the cause usually given for the rupture of the tube in tubal pregnancy, is only the determining cause, while underlying it is a gradual change in the composition of the tissues of the tube. The cause of this change is the destructive action on the maternal tissues of the elements of the fetal villi. These gradually penetrate the wall of the tube and destroy the cells, and the wall becomes softened and replaced with tissue that is poorly nourished, with imperfectly developed blood-vessels. Thus when hemorrhage does occur the distended tube is softened and prepared for rupture. The author brings forward the examination of the specimens in two cases observed by him, one of which shows the penetration of the villi into the maternal tissues where there was little hemorrhage and the relations of fetus to mother were not disturbed. In the other the hemorrhage was great, the parts were entirely displaced, and this process of softening could be recognized in the walls at the seat of rupture.—*Annali di Ostetricia e Ginecologia.*

Premenstrual Fever.—R. Romme, in speaking of the researches just published by Riebold, states that they show clearly that premenstrual fever is not limited to tuberculous patients, as this investigator has observed it in a large number of pathological conditions. The observations have been most carefully made. Out of eighty-seven cases of fever which were clearly premenstrual, thirty-seven were noted in tuberculous women. In the other patients diverse affections existed. There was a group of patients convalescing from various infectious diseases, such as scarlet fever, diphtheria, acute rheumatism, angina, and typhoid fever. Premenstrual fever appears more often in tuberculosis than in any other affection. According to Riebold's conclusions, every woman who during the three days preceding menstruation shows a temperature of 37.5° C., should be carefully examined by a physician, for it is the duty of the latter to determine the nature of the disease which for some time demonstrates itself only by this premenstrual fever.—*La Presse Médicale.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, September 22, 1906.

"JUST ENOUGH OF LEARNING TO MISQUOTE."

WE are disappointed in the secretary-editor of the American Medical Association. We had supposed he had at least the acumen, if not the conscience, to avoid misstatements which are easy of disproof; but it seems he has not even that. Six columns of the *Journal* of September 15 are devoted to a pretended review of the part the MEDICAL RECORD has taken in opposing the policy of concealment in the management of the Association, and in nearly every line the writer misquotes from this journal or charges us with statements which we have never made. We cannot, in a column or two, which is all we can in decency impose upon our readers in so personal a matter, note all the infractions of truth which occur in this long article. Nevertheless it is due the members of the American Medical Association, so many of whom are readers of the MEDICAL RECORD, that we should note and disprove a few of these astounding prevarications.

The editorial begins with the now hoary old falsehood that the MEDICAL RECORD has attacked the American Medical Association. The secretary-editor, in his reiteration of this charge, can only be wilfully saying what he knows not to be so in order to mislead such of his readers as have not the privilege of reading also the MEDICAL RECORD and so learning the truth for themselves. The insinuation is made that the "attacks on the Association" were inspired by a falling off in the number of subscribers to the MEDICAL RECORD. This is a stupid guess, for if it were true (which it is not, for there has never been a time in the history of this journal when its circulation was increasing so rapidly as now), it would have been the height of folly to adopt a course which might antagonize some possible subscribers. The writer of the editorial says we asserted "that the House of Delegates at Boston was dissatisfied with the Board of Trustees and that it was denied details regarding the business of the Association." Such a statement is staggering. It is an absolute falsehood made out of whole cloth, without the flimsiest foundation of fact. The fabrication is as foolish as it is knavish, for it is so easy of disproof by comparison with the files of the MEDICAL RECORD. Again, this garbler of quotations charges that we wrote that at Boston "a strenuous effort was made to get rid of the editor," and then characterizes the statement as "unqualifiedly false." What we wrote was: "It was rumored that a strenuous effort would be made to dismiss the secretary-editor." Really, if it were not unparliamentary we should have to apply an even stronger term than prevaricator to the man who has deliberately and in pure malice changed this quotation in order to make his point. The editor admits that there was opposition to him at Boston, but says "it was limited to the horde of nostrum vendors who have been getting rich by humbugging and deceiving our profession, and the owners or attachés of those medical journals nourished by the same brood, who allow themselves to be used as the mouthpieces and tools of proprietary interests." It is only three months ago that the secretary was cowering under the lash of the stinging rebuke administered by Dr. Vaughan and was seeking by any means to escape the consequences of his outrageous acts; yet now he has taken heart of grace and dares again to insult his masters and to characterize the many honorable members of the Association who have disapproved of his methods as "the mouthpieces and tools of the proprietary interests."

With a brief reference to a purely personal matter we shall have done. The writer of this editorial in the *Journal*, whoever he may be—the editor is in any case responsible for the misstatements it contains—says that the editor of the MEDICAL RECORD never attended a meeting of the American Medical Association. For eight or ten years he attended every meeting of the Association, but this was while the now secretary-editor was a student in the Hahnemann Medical College of Chicago or was engaged in homeopathic practice, and so naturally we did not meet. Again he says the editor of the MEDICAL RECORD became a member of the Association in March, 1906, which is true enough. In company with so many of his colleagues in New York State, he would not subscribe to the Code of Ethics which declared Dr. Simmons and his fellow practitioners unfit to associate with regular physicians, and so he could not join the Association until it had thrown over that curious old document. He was registered, however, at the meetings, paid his dues, and enjoyed all the privileges of a *quasi* associate member. He was ready to join the Association when the rules of this body should be changed so as to conform to the requirements of the physicians of New York State, and he became a member as soon as that was done.

It is not the province of medical journals to bandy personalities, and we shall endeavor not to tax our readers' patience again by noticing any further unveracities in which our disesteemed contemporary may indulge. What criticism the MEDICAL RECORD has made of any official of the Association has been inspired by a sense of duty, for the columns of the *Journal of the American Medical Association* are notoriously closed to all communications which reflect in any way upon the acts of the secretary, and it is only in the independent journals that the truth can be spoken. If the managers of the Association adhere to their recently announced policy of open dealing with the members we shall be content with the result of our labor, and they may count upon our cordial support. But they must give their editor-secretary a copy of the Ten Commandments with the ninth underscored, and see that he, or whoever writes his editorials, observes its admonition in his public utterances; otherwise he may some day bring them as well as himself into danger of the judgment.

THE ORIGIN OF SLEEP.

The nature and origin of sleep have occupied physicians and physiologists since the time of Hippocrates, and, strange as it may seem, we are still in more ways than one "in the dark" as to the exact mechanism of this common, every-day phenomenon of life.

The greatest variety of theories have been put forward to account for sleep. The psychological theory (Manaseine) is that sleep is a time of rest for consciousness. The histological theory (Rabe, Ruickard, Lépine, Duval) attributes sleep to the retraction of the dendrites of the cortex cells, interrupting the connections of neurons. Howell's hypothesis is that sleep is due to cerebral anemia from a fall of blood pressure when the tone of the vessels is relaxed; but the objections to this are numerous. For example, somnifacient drugs may increase the blood supply to the brain; sleep is favored by small doses of alcohol, by the recumbent posture; the face is reddened in sleep, etc. Czerny, and after him Schleich, have concluded, in fact, that sleep is due to cerebral hyperemia.

The chemical theory of sleep is also interesting. Pflüger believes that sleep is caused by lack of oxygen in the brain. According to Dubois, sleep is induced by an accumulation of carbon dioxide; according to Obermeister and Preyer, of toxic substances in the central nervous system. The chemical theory holds that sleep is induced by toxic substances generated by the nervous system itself, and yet it is a matter of common knowledge that men who work hard with their brains sleep far less than the average day-laborer.

And now comes Dr. Alberto Salmon,* who maintains that sleep is induced by the internal secretion of the pituitary body. He submits that somnolence is characteristic of tumors of the pituitary body, with or without acromegaly, provided no degeneration of the gland takes place, and of myxedema, when the gland usually becomes enlarged. In sleeping sickness a hypertrophic pituitary body is found. Somnolence is also noted in infectious diseases in which there is chronic meningitis and there is congestion or inflammation of the pituitary body (influenza). Certain intoxications and autointoxications (pilocarpine, morphine, gastric and hepatic poisons) experimentally induce hypersecretion of the pituitary and cause somnolency. Obese persons are often very sleepy, and functional disturbances of the hypophysis cerebri are not infrequently noted in these persons. Somnolence is also found in all conditions causing a congestion of the hypophysis, such as epilepsy and injuries to the head.

On the other hand, insomnia is noted in tumors of the hypophysis with degeneration of this body; in the late stages of acromagaly, when the gland is partly destroyed; in Graves' disease, in which at autopsy the gland is found atrophic; in certain forms of diabetes, in which the glycosuria is secondary to lesions of the gland and of the glycogenetic centers situated in its neighborhood. Insomnia also exists in all conditions which favor atrophy or destruction of the pituitary body, as in old age, in inanition, in arteriosclerosis, in severe acute or chronic infections and intoxications (phthisis and cerebrospinal meningitis, atropine poisoning, chronic morphine and alcohol poisoning, etc.) Sexual and nasal diseases also give rise to insomnia, which is sufficiently explained, according to Salmon, by the close relations of the pituitary body with the sexual organs, and its proximity to the nose.

All these considerations, together with the connection of the pituitary gland with the nutrition of the nerve centers, serve as a basis for Salmon's theory that sleep is due chiefly to the secretion of the pituitary gland. The isolation of this secretion and the injection of it experimentally into animals to induce sleep would, if successful, offer a more convincing proof of this theory than any adduced as yet by Salmon.

*Sull' Origine del Sonno; Studio delle Relazioni tra il Sonno e la Frunzione della glandula Pituitaria, Florence, 1905.

CONTROL OF WATER AND MILK SUPPLIES.

The most important subject considered in the Section of State Medicine, at the recent meeting of the British Medical Association, was that of the control of water and milk supplies. Perhaps polluted water and milk are the most fertile sources of disease known to civilization, and any suggestions as to improving such supplies should be of the greatest interest. At the meeting in Toronto there were present eminent sanitarians from Great Britain, the United States, and Canada, and consequently the views ventilated were of special value. The question of an improved water supply in both urban and rural districts has been agitating the minds of the medical profession and a portion of the laity of America for some considerable time. In some cities effective steps have been taken to remedy conditions as regards water supplies, which had become a public scandal and a grave menace to the health of the community. In other cities an unfortunate and unhealthy state of affairs continues to exist, and typhoid fever, the unvarying sequel of neglected water, is still far too common in this country.

In Great Britain the water supplies, as a rule, are well guarded, and typhoid fever has of late greatly decreased in that country. So far as the milk supply of Great Britain is concerned, however, matters are on a very different footing, for America is as far ahead of Great Britain in the control of her milk supply as Great Britain leads America in her care of water. Thus each country had much to learn of the other.

One of the best papers read was by Dr. H. D. Holton, secretary of the Vermont State Board of Health. Dr. Holton advocated the careful analysis and examination of all sources of public water supplies, and spoke very strongly against the custom followed by individuals or by municipalities of discharging sewage into rivers or other bodies of water. Such a practice would sooner or later affect the purity of the supply, and serious results would probably ensue to those who used the water. Dr. Holton further recommended that sewage should be filtered, as many of the intestinal and kidney troubles from which so many people suffered might be traced to the pollution of water supply by sewage. Prof. Glaister of Glasgow University emphasized the importance of proper control of the area whence the water supply is procured. In Scotland the care-

ful exercise of such precautions had practically abolished water epidemics in that country. The law in Scotland reads that no individual or community is permitted to pollute any stream, so that the down-stream user does not receive the water in its original state of purity. Referring to filtration, Prof. Glaister pointed out that while the method would remove a large percentage of impurities, it would not do so without adequate reservoir accommodation, and a large sedimentation area.

Dr. T. A. Starkey, Professor of Hygiene at McGill University, dealt with the question of the pollution of water supplies by sewage, and gave some conclusions reached by him as a result of his observations for a series of years in regard to the gradual deterioration of the water in the Ottawa and St. Lawrence rivers. For many years it has been a popular belief, and even among sanitarians, until recent times, it has been the common view that large rivers completely purify themselves in time from pollution by sewage. Prof. Starkey pointed out that, considered bacteriologically, the so-called purification was merely dilution, and the pollution was not got rid of. The remedy for the pollution obviously was control of the sources of water supply. He did not wish to be an alarmist, but he was compelled to admit that the condition of Canadian rivers was becoming dangerous. All the speakers agreed that the importance of purification of sewage and of the filtration of water could hardly be over-estimated.

The question of milk control, owing to the length of time occupied by the discussion of water supplies, was debated in a somewhat too abbreviated manner. Dr. R. Harcourt of Guelph, Ontario, who read the first paper, was altogether a pessimist in regard to the present methods of handling and delivering milk in Canada. He was of the opinion that if a commission were appointed to investigate the conditions under which milk was handled and delivered to the consumer, the report would be worse than that relating to the meat-packing establishments of Chicago. The consumer, he opined, had the right to demand milk which, if maintained at sixty degrees or less, would keep for twenty-four hours, and that it be free from flavors. The advisability of establishing a standard required for milk, the price of which should depend on the quality, was considered. The addition of preservatives of any kind was deprecated as injurious to public health, and in some circumstances deleterious to the food quality of the milk. Prof. Glaister gave much valuable information regarding the model methods by which the purity of this article of food could be assured to the consumer. But, as said before, the discussion on milk was hurried over, and the subject did not receive the attention which it rightly deserved.

However, these outstanding points in the discussions on water and milk may be observed. That in America water supplies, as a rule, are comparatively neglected to the great detriment of the health of the community at large. That in America, while, of course, the situation as regards the control of the milk supply is by no means ideal, in the cities milk is handled and delivered with far more care than in Great Britain generally. It therefore behooves the people of this country to insist upon having a pure water supply, while it would be to the great advantage of the British people if their system of milk control were thoroughly reorganized.

A Novel Plastic Operation.

When the necessity of covering cranial defects was fully recognized, it was believed that the osteoplastic method advocated by Mueller and Koenig solved the problem in most instances. There are cases, however, in which a proper bone flap cannot be made, because the diploë or the surrounding tissue is excessively thin, and then it becomes necessary to fall back on the various heteroplastic procedures which have been devised for this purpose. One of the serious drawbacks connected with the latter is the possible production of adhesions. When localized cerebral symptoms are present after an injury to the head and they are due to a cicatricial process, no permanent cure can be expected unless reunion can be prevented after extirpation of the cicatrix. As pointed out by Carl Beck in an article in the *Annals of Surgery* for August, 1906, the apposition of brain and periosteum which takes place when the usual osteoplastic flap is employed, must necessarily result in the production of more or less unyielding scars. This might be obviated by a plastic transposition of the dura, but such a procedure is, of course, possible only in slight defects. Beck has suggested that the temporal fascia affords a material which possesses no marked tendency to the formation of adhesions, and he has applied his own suggestion in two cases. The flap which he employs includes the fascia and underlying periosteum, and when it is folded over the exposed brain the latter is covered by fascia, while the periosteum remains on top. A protecting lid is slowly formed, which, although it does not attain the thickness of a bone flap, seems to afford ample protection. In the two cases which he reports convulsions were present following an injury which involved the parietal region. The procedure described was readily carried out in each instance, and there was little reaction. The time which has elapsed since the operations, only a few months in the first case, is really too short to warrant a verdict regarding the disappearance of the convulsions, but the method is certainly sufficiently simple and its theory sufficiently logical to stimulate to further trials by other operators in selected cases.

The Protective Value of the Thyroid Gland.

The fact that an enlargement of the thyroid gland has been observed during the course of many of the infectious diseases makes it probable that this organ is also concerned in the protection of the system in addition to its other possible functions. Vincent (ref. in *Wiener klinische Wochenschrift*, No. 31, 1906) finds that in rheumatism there is also apt to be found a painful enlargement of the thyroid. Although true rheumatic thyroiditis is rare, the other condition referred to frequently constitutes a feature in the clinical picture of moderate and severe cases of acute articular rheumatism. The swelling and tenderness involve both lobes, come on during the early stages of the disease, and subside with the fever and the local joint pains, but return with every recurrence of the original trouble. In the milder attacks, as well as in the chronic cases, these changes in the thyroid are not observed. Vincent believes that the swelling in the gland does not merely denote an involvement of the organ in the rheumatic process, but is an expression of its increased function in the fight against the infection.

News of the Week.

Dedication of the Harvard Medical School Buildings.—On September 25 and 26 the new buildings of the Harvard Medical School on Longwood avenue will be dedicated, and the exercises are to be made the occasion of a reunion of as many as possible of the graduates of the institution. On the first day the buildings will be inspected and formally accepted, but the more elaborate ceremonial will take place on the following day at Sanders' Theater. Addresses will be delivered by President Charles W. Eliot of Harvard and by Professor William H. Welch of Johns Hopkins University. There will also be the presentation of greetings from other institutions and the conferring of honorary degrees. Later in the day the triennial banquet of the Harvard Medical Alumni Association will be held in Memorial Hall, at which it is expected that over 1,000 alumni will be present.

New Plans for a Filtration Plant.—The Water Commissioner, under authorization by the Board of Estimate, has decided on plans for a city filtration plant to be erected at the Jerome Park reservoir, at an estimated cost of $12,000,000. It is proposed to build the filtration plant over the Jerome Park reservoir, completely covering it, and the capacity of the sand beds is expected to be 380,000,000 gallons daily. The department has also decided to erect an experimental plant at Jerome Park, to cost $12,000, to discover the best processes for the elimination of bacteria that a sand filter cannot take care of.

Barren Island Reduction Plant Rebuilt.—The Street Cleaning Department has announced that the city's garbage reduction plant on Barren Island, which was completely destroyed by fire last spring, has been rebuilt and will shortly be in operation again, so that it will no longer be necessary to resort to the expedient of dumping the city's refuse at sea. The new plant is much larger and more thoroughly equipped than the old one, and comprises 22 boilers, 100 digesters, 25 presses, and 25 receiving tanks. The vapors arising from the work are to be disposed of in an inoffensive manner by the erection of a high smokestack.

Trachomatous Immigrants.—The immigration authorities have discovered at Philadelphia what they believe to have been a conspiracy to land in this country large numbers of Armenians who are now in London, all of whom, it is alleged, are suffering with trachoma. Three Armenians have been indicted in Philadelphia for attempting to bribe an immigration inspector through whose intervention it was hoped to introduce into the country the diseased immigrants. The Commission of Immigration estimates that there are in the neighborhood of 10,000 cases of trachoma among the aliens of New York.

Yellow Fever Prophylaxis in Central America.—The report of the Honduras health officials recently published indicates that the campaign against yellow fever in that country has met with great success. It is stated that precautions have been carried almost to extremes, houses of the poor in some cases having been burned to destroy filth and new houses having been supplied in their places. Frequently clothing worn by beggars has been burned, better and cleaner material replacing the burned garments. Cisterns have been screened, and sulphur has been burned indoors and petroleum spread over the surface of stagnant pools. Weeds have been destroyed in great quantities. As a result in communities where last year fifty or more cases of yellow fever were reported not one case has developed during the last two months.

Baron Takaki's Return to Japan.—Prof. Baron Takaki, who had left Yokohama the last winter, for Columbia University, New York, to give a lecture there by the request of that institution, went to Europe after successful close of his mission. After spending about three months in looking through all the chief hospitals and institutions he went back to United States again. Finally he spent some time in Canada, and embarked on the steamer *Empress of China*, of Pacific Steamship Company, on the 2d of this month, and on the 16th inst. the steamer anchored at the Yokohama harbor, where he landed immediately and hastened to the railway station to take a train for Tokio. On the up train of 1:35 P.M. the Baron arrived at Shimbashi station. He was heartily received there by distinguished representatives of the medical profession of the metropolis. Especially a body of the students of Tokio Charity Hospital Medical School, which consisted of about 200, regularly fell in before the Baron at the platform and unanimously shouted the *Banzai* for him under the order of their instructor. Thus after receiving the salutation of those who attended there to meet him he left the station by a carriage prepared for him for his residence, Nishikonyacho Kyobashiku. Those who crowded the station this day numbered about 400 persons. As the information of his return was rather sudden this day, many persons who passed the return time of him unknown were very numerous.—*Sei-I-Kwai Medical Journal.*

Gift to the Presbyterian Hospital of Chicago.—Recently Dr. D. K. Pearsons donated an additional $5,000 to the fund for the building of the new Presbyterian Hospital, and it is thought that the entire amount required will soon be subscribed. To complete the institution $400,000 altogether will have to be raised. Dr. Pearsons' gift brings the total amount given to $390,000, leaving only $10,000 to be subscribed.

Chicago Lying-in Hospital Plans New Structure.—The Chicago Lying-in Hospital and Dispensary proposes to build on its new property at the northwest corner of Vincennes avenue and Fifty-first street. The directors are planning the erection thereon of a maternity hospital which will be a model for such institutions and will cost between $150,000 and $200,000. It is estimated that the new hospital, with its sixty beds, will care for 1,200 babies every year. At present the one on Ashland boulevard is caring for about 400 patients, while the three dispensaries, sending nurses and physicians into the homes of the poor, take care of about 1,400.

Homeopathic Committee Opposes Single Board Plan.—At the Atlantic City convention the Interstate Committee of the American Institute of Homeopathy in its report urge the homeopathic societies of the country to advocate separate State Examining Boards in all States where they do not now exist, and to oppose legislation providing for the consolidation of the regular, homeopathic, and eclectic boards.

Race Suicide in Connecticut.—The editor of the *Berlin* (Conn.) *News*, in commenting on the fact that during the past year no boys have been born in that town, offers a year's subscription as a reward to the parents of the next male child.

Illness Due to Dried Beef. — Ten persons in three different families of Kalamazoo, Mich., are reported to have been made seriously ill as the result of eating dried beef said to have come originally from one of the large packing houses. The supposition is that the illnesses were caused by the presence of preservatives in the beef.

A New Measles Pavilion.—Plans have been prepared for a new measles pavilion to be built by the city on the grounds of the Kingston Avenue Hospital in Brooklyn, and bids will be opened on September 24 by the Board of Health.

Report of Cook County (Ill.) Coroner for August.—The table of deaths from other than natural causes during the month, as reported by the Coroner of Cook County, was as follows: Suicide, 30; drowning, 29; heat prostration, 27; railroad accidents, 26; homicide, 14; street car accidents, 13; lightning, 1, and scenic railway accident, 1.

Anthrax is reported to have appeared in central Delaware among the live stock, and many animals have died from this cause. The State authorities have ordered all the carcasses of dead animals burned and are causing animals exposed to be inoculated.

Work of Visiting Nurses' Association.—During August the Visiting Nurses' Association cared for 1,227 patients, and the nurses have made 5,738 visits. The diseases cared for were tuberculosis, typhoid fever, and cholera infantum.

Plea for the Restoration of the Canteen.—The short-sightedness of those through whose misguided zeal the army canteen was abolished has been again scored by Lieutenant-General H. C. Corbin, commanding the Northern Division, who, in his annual report published on September 13, points out the physical and moral perils besetting the soldier who, deprived of any opportunities for social relaxation within the barracks, is forced to seek enjoyment in the vile haunts always to be found in the neighborhood of army posts.

Opening of Columbia University.—The opening exercises of the academic year 1906-7 of the College of Physicians and Surgeons will be held in the Lower Lecture Room on Thursday, September 27, 1906, at 3 o'clock P.M. After a brief address of welcome by the president of the university an address will be delivered by L. Emmett Holt, M.D., LL.D., Sc.D., Carpentier Professor of the Diseases of Children, upon "Medical Ideals and Medical Tendencies."

Argyria.—A correspondent asks for information regarding the discoloration of the body produced by taking pills of nitrate of silver, and whether it is possible to remove it. Twelve years ago, he says, one of his patients took many such pills, but within a year his color seems lighter. His health is good, still he is very dark.

Missouri Valley Medical Association.—The following were elected as officers of this society at the session held at Council Bluffs, Ia., on September 7: *President,* Dr. O. B. Campbell, St. Joseph, Mo.; *First Vice-President,* Dr. M. F. Milroy of Omaha; *Second Vice-President,* Dr. C. O. Thienhaus, Milwaukee; *Treasurer,* Dr. Donald Macrae, Sr., of Council Bluffs; *Secretary,* Dr. Charles Wood Fasset of St. Joseph, Mo. Omaha was chosen for the next meeting, to be held on the fourth Thursday in March.

Cumberland Valley Medical Association. — At the fourth annual meeting of this society, held in Chambersburg, Pa., on September 4, the following officers were elected: *President,* Dr. C. F. Palmer, Chambersburg; *First Vice-President,* Dr. D. A. Watkins, Washington county; *Second Vice-President,* Dr. J. C. Davis, Cumberland county; *Third Vice-President,* Dr. C. M. McLaughlin, Greencastle; *Secretary,* Dr. J. J. Coffman, Scotland; *Assistant Secretaries,* Drs. D. H. Smith of Cumberland county, H. C. Devilbiss of Chambersburg, D. C. R. Miller of Mason and Dixon; *Treasurer,* Dr. J. J. Koser of Shippensburg.

Western Surgical and Gynecological Association.—At the final session of the sixteenth annual convention of this association, held at Salt Lake City on September 2, St. Louis was selected as the next place of meeting, and officers were elected as follows: *President,* Dr. C. W. Oviatt of Oshkosh, Wis.; *Vice-Presidents,* Dr. S. C. Baldwin of Salt Lake and Dr. Jabez N. Jackson of Kansas City; *Secretary and Treasurer,* Dr. A. T. Mann of Minneapolis.

Claiborne County (Miss.) Medical Association.—A society with this name was organized at Port Gibson, Miss., on September 3, and the following officers were elected: *President,* Dr. W. D. Redus; *Vice-President,* Dr. J. F. McCaleb; *Secretary and Treasurer,* Dr. George W. Acker.

Colorado Homeopathic Society.—At the twenty-first annual convention of this society, held at Denver on September 6, the following officers were elected: *President,* Dr. F. A. Faust of Colorado Springs; *First Vice-president,* Dr. A. C. Stewart of Denver; *Second Vice-President,* Dr. Clinton Enos of Denver; *Secretary,* Dr. E. B. Swerdfeger of Denver; *Treasurer,* Dr. James B. Brown of Denver.

Obituary Notes.—Dr. PHILLIP S. WALES, Medical Director, U. S. N., retired, died of cancer, in Paris, France, on September 15, after a long illness. He was born at Annapolis in 1837, and after graduating from the University of Maryland entered the United States Navy as assistant surgeon. He was made a surgeon in 1861, and served during the Civil War at the naval hospital at Norfolk and on the steamer *Fort Jackson.* He was made a member of the Board of Examiners in 1873, and later occupied the posts of medical inspector, chief of the Bureau of Medicine and Surgery, and medical director. He was one of the physicians who attended President Garfield in his last illness. He was retired from the service on account of age in 1896, since which date he had spent most of his time in Washington.

Dr. LEROY M. YALE of this city died suddenly of apoplexy on September 12, at his summer residence in Quissett, Mass. He was born in Vineyard Haven, Mass., sixty-five years ago, and was graduated from Columbia College in 1862, receiving his medical degree from Bellevue Medical College four years later. He had been the editor of several publications and was the author of several treatises on medical subjects, for the most part dealing with pediatrics.

Dr. M. E. PAGE, an eye and ear specialist, of Oswego, N. Y., died on September 10, at the age of forty years. Dr. Page was born in Broome county and received his medical education in the Bellevue Hospital Medical School.

Dr. JAMES A. FINN of Roxbury, Mass., died on September 2, at the age of sixty-five years. He was a native of Boston and was graduated from the Harvard Medical School in the class of 1875.

Dr. JAMES H. PEABODY of Omaha, Neb., died on September 9, at the age of seventy-three years. He was born in Washington, D. C., and received his medical degree from the University of Georgetown in 1860. He served as assistant surgeon during the Civil War and in 1864 was made medical director of

the district of Nebraska. In 1866 he began practice in Omaha and had resided there ever since that date.

Dr. JOSEPH H. DRAKE of Des Moines, Ia., died on September 8, at the age of sixty-one years. Dr. Drake was born in St. Thomas, Ont., and had practised in Des Moines since 1890.

Dr. FRANK H. DUNBAR of Swanton, Vt., died on September 6, of gallstones, at the age of thirty-seven years. He was graduated from the Medical College of Vermont in the class of 1903 and had practised in Swanton since that time.

Dr. EDGAR A. BROOK of Bonner, Mont., died on September 4, at the age of forty-five years. He had practised in several Montana towns for many years and several years ago was city health officer in Butte.

Dr. WILLIAM R. CHEEVER of Kenosha, Wis., died suddenly on August 30, at the age of thirty-eight years. He was a graduate of the College of Physicians and Surgeons of Chicago and had practised in Kenosha for a number of years.

Dr. D. J. MCCABE of Berlin, N. H., was instantly killed in a runaway accident on September 16, while on his way to visit a patient.

Dr. EVERARD D. FERGUSON of Troy, N. Y., died after a brief illness on September 8, at the age of sixty-three years. He was born in Moscow, N. Y., and received his medical degree from Bellevue Hospital Medical College in 1868. He was surgeon of Clinton Prison at Dannemora for three years and then took up his residence in Troy in 1878. Dr. Ferguson took an active part in organizing the New York State Medical Association, and he served as its secretary during several years. He was a member of the House of Delegates of the American Medical Association and was at one time vice-president of the Association.

Correspondence.

SUICIDE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Apropos of Dr. Geo. M. Gould's article, "The Mysteries and Sources of Suicide," in the MEDICAL RECORD of September 8, 1906, it might be interesting to inquire: Is not the question of suicide in by far the greater number of instances a psychological problem? As the writer suggests, statistics are wholly unreliable as to the cause which it is frequently impossible to know. Furthermore, there are many cases of suicide reported as deaths due to other causes. Relatives of a suicide regard it as a stigma, and endeavor to conceal the facts of the case. The would-be suicide has the same feeling, and contrives to make the cause still more obscure. The physician in attendance is led to certify as a cause heart failure, ptomain poisoning, apoplexy, overdose of hypnotics, etc., when he has misgivings as to the real cause. Under those circumstances he is compelled to refrain from pronouncing a case of death suicide, for whatever he believes he could not prove, and would bring condemnation on his head.

The causes other than disease that lead to suicide furnish an important educational problem. Some have sought to discover why suicide should increase *pari passu* with civilization. It is not because of the increase of disease, as the mortality rates show decrease. It is not necessarily due to physical disease resulting from the various forms of strenuous life, but originally from the psychological effects of mistaken ideals, unruly passions, ungovernable ambitions, etc. Drug addictions are not a primary cause but are formed at a later stage, which finally terminates in suicide. It is remarkable how rarely an invalid commits suicide, and physicians wonder that they do not oftener adopt that form of death. I once knew of a hopeless morphine habitué having been persuaded by a member of the family to commit suicide without avail. Some believe that suicide never occurs apart from mental or physical disease. To understand the final causes of suicide, it is necessary to understand the reasons for our clinging to life: (1) There is the animal instinct of the fear of death, which exists in all the higher forms of life. (2) The existence of a belief in happiness from living. (3) The belief that suicide is a moral wrong. (4) The fear that death may not be a total annihilation.

One or more of these reasons may frequently be overcome, but when all are overcome there is nothing left to be done but commit suicide. As to the first cause, any philosophy or form of stoicism is sufficient to overcome the instinctive fear of death. The pessimistic philosophers can easily eliminate the second cause as well as the first, but it is not so easy to do away with the third and fourth, for no sane person will argue that suicide is not morally wrong. Hamlet eliminated all but the fourth reason, and there he balked, and the same uncertainty makes many hesitate. It is easy to understand how a diseased condition would make predisposition active.

OUR LONDON LETTER.

(From Our Special Correspondent.)

A SANITARY CONFERENCE ON MEAT SUPPLY, ETC.—TUBERCULOSIS IN MUMMY DUST—PROPAGATION OF LUNACY—THE ANTIS' CAMPAIGN—ABSORBENCY OF MILK—THERMOPILE FABRICS—RAY LANKESTER.

LONDON, August 31, 1906.

A CONFERENCE of medical officers of health and others was held on Wednesday to consider measures for providing the public with meat from healthy home-bred cattle and sheep. The chairman, Dr. Pickett-Turner, urged the importance of a healthy meat supply and proposed that it should be organized, that public abattoirs only should be permitted and conducted under supervision of medical officers of health. In his opinion tuberculosis was derived entirely from cattle which had been fed on diseased grass. Jews, he said, owing to their method of slaughter, ate practically no tuberculous meat, and their death rate from the disease was only a third of the general rate. Dr. Fitzgerald Arthur explained the scheme which it was thought would receive the approval of the medical profession and provide the public with a guarantee of healthy food. It was to be run on commercial lines, to be started near London, bring cattle from Ireland, graze them in Essex, and stall-feed for a time before killing in the public abattoirs. Mr. D. Tallerman (secretary) said cold storages for dressing the meat were to be attached to the abattoirs, and the society proposed to do such work as farmers, butchers, and others required. A general committee, with power to add to its numbers, was appointed to carry out the scheme.

Recurring to the opinion of Dr. Pickett-Turner, he might like his attention directed to Dr. Sornac's recent monograph on the spread of tuberculosis. That writer attributes the increase of the disease in the past 100 years to the disinterment and shipment of mummies from Egypt. He says there are tubercle bacilli in the dust of every mummy case, and the workmen and scholars who began the exhumation fell victims in large proportion. The Napoleonic invasion of Egypt coincided with the outbreak of tuberculosis, which rapidly spread all over Europe with the return of the army and the concurrent distribution of mummies and mummy dust.

Yesterday a discussion took place at the Lancashire Asylums Board on the increase in lunacy, and a resolution was unanimously passed expressing alarm and authorizing steps being taken to ascertain the best means of preventing lunatics from propagating their species. The mover argued that the present humane system of treatment in asylums led to a large number being discharged as cured and set free to propagate and so keep up the supply of fresh cases. Asylums, he said, were degenerating into places where the insane were "doctored up" and then sent away to breed other cases, who followed their parents into the asylums, which discharged annually 14,000 lunatics to spread their mental taint.

Dr. J. M. Rhodes took exception to the idea that this was rapidly becoming a mad world. He admitted that epileptics propagated rapidly, but the epilepsy which produced mental disease had steadily decreased since 1860, and people should contrast the present facility of entering asylums with the time when a certificate would not be obtainable unless the patient were dangerous. Now the benefit to the patient is the first consideration. He had consulted with French, Scotch, American, and German lunacy commissioners and found they all agreed that the increase of lunacy was more apparent than real. Temperance and sanitation were beginning to tell, and through them we should strike at the root of the mischief.

In reply to this a member urged that when five out of eight cases in the asylums were hereditary it was time for the several boards to unite to bring about an alteration in the law which would enable cured patients to be detained or otherwise prevented from adding to the insane population.

The antis of various ilks are making the most of the dead season. Their campaign just now presents a series of slight engagements or pitched battles in the newspapers which avail themselves of the letters sent in accordance with the plan. Many of these little discussions are really started by the central anti-committees, and the leaders of certain minor papers are supplied by a syndicate in London, adapted for the differing politics of the papers. This is the reason why in different towns, if you notice these things, you find the same article. The correspondence of the antis is conducted in the same way. The fanatics about vaccination began this circulation of misstatements, and those about vivisection were not slow to take the hint. The advantage of it is obvious. A letter is inserted with all the appearance of being a spontaneous expression of opinion or even an inquiry. No answer from the locality in defense of the attacked party is to be expected. The local doctors are too busy in attending their patients to occupy themselves with local politics or the contents of the local sheets. Besides, their patients are sometimes most fanatically inclined and it would be idle to attempt to convince them. The parson and the 'squire may be hostile or politically agreed, but neither as a rule expects the doctor to engage in local polemics, and they would unite in disapproval if he did. So it happens that the circulation of misstatements goes merrily along and even the absolute falsehoods of the antis obtain wide credence among those classes of the community which are incompetent to judge, but as they have votes the parliamentary candidates listen and make promises which they know they cannot fulfill.

The great absorptive energy of milk is known as a general fact to all who have to do with its transport. It will acquire a fishy odor when the cans are in contact with fish on a railway journey, and the way in which it picks up flavors in a shop is remarkable and suggestive. MM. Bordas and Toutplain have been experimenting with a view of determining the rate at which it can absorb odors. Selecting formaldehyde, which can never be a normal constituent and is detectable in minute quantity, they found that milk would take up an appreciable quantity when exposed for a few minutes to an atmosphere containing only one of formaldehyde in 100,000. A vessel which had contained a dilute solution and subsequently had been carefully rinsed with water imparted enough to milk put in it to give a distinct reaction. The absorption seems most active in new milk, and it gradually becomes feebler the longer the milk is kept. These experiments fully justify the urgent statements which doctors have so long been accustomed to impress on their patients, especially at this season of the year, when outbreaks of maladies attributable to unclean milk are so frequent.

The use of electricity for heating receives a new illustration in "thermopile fabrics," which consist of a combination of textile and conducting threads. The inventor, M. Herrgott of Belport, claims that he has made several fabrics which are capable of giving out a heat of 70° to 95° F. By their use, heated by an electric current, foot-warmers can be dispensed with and rugs discarded. He even thinks that a general hot-air bath might be obtained. The local application of heat by such a plan would certainly present some advantages over older methods.

The virtual dismissal of Professor Ray Lankester from the Directorship of the Natural History Museum came as a shock to scientific men and excites much indignant comment. The decision appeared in the morning papers the day before he took the chair as President of the British Association. Technically the trustees of the museum may be right, that retirement is due at 60, but his predecessors were given further periods and he was brought from a far more lucrative office at Oxford to reorganize the museum. Thus is science dealt with in this country.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

THE DEUTSCHE AERZTETAG AND THE LEIPZIGER VERBAND—ADVANCING THE MATERIAL INTERESTS OF MEDICAL NON-TREATMENT OF APPENDICITIS.

BERLIN, August 28, 1906.

GERMAN physicians of all classes look forward with much interest each year to the meetings of the "Deutsche Aerztetag," since at such time many matters relating to the social position and the material interests of the medical profession are discussed. The thirty-fourth annual meeting was held this summer at Halle, being preceded, as usual, by that of the Leipzig Association, a society established to promote the material interests of the medical practitioners of Germany. At this meeting the President, Dr. Hartmann, outlined the work of the society during the past year; in that time it had without charge placed 1,286 substitutes and 518 assistants, and had established 354 in practice; it also conducted the physician's case in 129 disputes with lodges, and in the 98 of these in which a decision had been arrived at, the latter was adverse to the physician in only three. The railway administration has aroused general indignation by an order commanding all railway physicians to resign from this association. The cause of this is the effort which the Leipzig Association has been making to establish the right of a person injured by the railway to select his own physician, and not be compelled to accept the services of the company's doctor. Assistant physicians and ship surgeons, both of whom are very poorly paid, have asked the Association to agitate for an amelioration of their lot. The Association voted to take up the cause of its petitioners and to open negotiations with the steamship companies.

The day after the meeting of the Leipziger Verband the Deutsche Aerztetag was held. Of the 371 affiliated societies, with 22,223 members, 294 societies, with a membership of 20,523, sent 487 delegates. The most important paper of the meeting was one by Pfeiffer of Weimar, on the relation of the medical profession to the workingmen's insurance law. He contended that no physician should make a contract with lodges or workingmen's associations until the terms of the contract had been passed upon by a special contract committee of the Deutsche Aerztevereinsbund. Several other papers were read, but the subjects discussed were chiefly of local or rather national interest only, and so I need not deal with them here.

A long discussion on the treatment of appendicitis has occupied the last three sessions of the Berlin Medical Society. Prof. v. Bergmann dwelt upon the necessity of an early diagnosis, upon which, of course, early operation depended. Kraus noted the discrepancy often found to exist between the clinical symptoms and the pathological changes. In many cases what is called an abortive attack is simply one of colitis; in this we find a swelling in the right inguinal region, pain on pressure, and muscular rigidity, just as in true appendicitis. The pain may be due to a number of conditions—toxemia, neuralgia of the skin or of the abdominal viscera, pressure of a tumor, and peritonitis. The mortality of the so-called conservative treatment of appendicitis in children is very great, Kraus said, yet he did not believe that operation was indicated in more than half the cases. Heubner said that the indications for operation were sudden onset, rapid pulse, and an anxious facies; these symptoms pointed to an appendicitis hæmorrhagica. Orth said that the statistics of appendicostomy showed that in from 9 to 10 per cent. of all operations the appendix was normal in appearance. Even in very grave cases of appendicitis a restitution to anatomical integrity was not impossible. Israel said that appendical pain, sensitiveness in the right iliac region, and fistulas often remained after operation. He would not advise an internal operation after suppurative appendicitis, or if there have been no symptoms for at least two years. Rotter favored the primary operation, and thought mistakes in diagnosis were less common than some claimed them to be, though he believed they could not be avoided in about 2 per cent. of the cases. Landau discussed the relation of appendicitis to diseases of the internal genital organs in women, and said that although the symptoms were practically the same in both conditions, the differential diagnosis was nevertheless not usually very difficult. Olshausen did not agree with the last speaker, that the differential diagnosis of appendicitis and salpingitis was a simple matter. The general consensus of opinion was that a primary operation should be undertaken as early in the course of the disease as possible. In order to collect satisfactory statistics, a committee was appointed to draw up a list of questions regarding the disease and its treatment, to be sent to all Berlin physicians, and if possible to all medical practitioners in Germany.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

ESTIMATION OF BLOOD PRESSURE—THE PHOSPHATIDS OF THE HEART, CUORINE VESICAL TUBERCULOSIS—FOUNT IN-RAYS IN TRIGEMINAL NEURALGIA.

COPENHAGEN, Sept. 1, 1906.

DR. H. T. BING has published an interesting investigation into the value of the generally used clinical methods for estimation of the blood-pressure. He used an apparatus of the Riva-Rocci type, but his results are claimed also to apply to the apparatus of Masing-Sahli-Strassburger, and that of Hill and Barnard. The question under discussion is whether the tension, shown by the manometer, the apparatus being applied to the arm, indicates the end-pressure or the lateral pressure in the brachial artery. In the first case variations of the manometer readings also indicate variations of the aortic pressure, and may consequently give valuable information as to variations of the heart-labor. In the second case, the variations of the manometer

readings may have been caused by changes in the state of contraction of vessels peripheric to the apparatus. Thus, a sudden considerable relaxation of the minor arteries peripheric to the place constricted by the apparatus would cause a lowering of the tension, as indicated by the manometer, not necessarily coinciding with a decrease of the aortic pressure, as compensation might arise by contraction of vessels in the splanchnic area. Now, Bing shows that the method gives the lateral pressure in the brachial artery and not the end pressure. He applies a Riva-Rocci apparatus to each arm, and to one of the forearms a thermic irritant. The manometer attached to this arm then indicates a decrease of the blood-pressure not indicated by the other arm's manometer, as would have been the case had the manometer given the variations of the end pressure in the brachial artery. Consequently the many investigators who claim to have demonstrated with the aid of these apparatuses, that the heart labor is influenced in a determined direction by certain procedures (hydropathic, phototherapeutic, administration of drugs), may have been mistaken. At least the proofs hitherto alleged by the authors cannot longer be considered to obtain, and there is again a wide field for new researches.

Uncommonly painstaking and conscientious researches into the phosphatids of the heart have been made by Dr. A. W. E. Erlandsen. In the standing contest between the English chemist Thudichum and most of the other European chemists who have worked with the substances of the lecithin group, Erlandsen follows Thudichum on many important points. He shows the necessity of changing the old definition and division of the lecithinoid substances for a new and more correct one, based on more stringent chemical principles. Thoroughly to discuss his results here would lead too far, but I may be permitted to mention as one of the most important the discovery of a hitherto unknown substance, cuorine, appertaining to the group, named by the author by the sesquipedalian word monoamido-diphosphatids. This cuorine is found in the heart muscle, while other muscles contain only traces of it. Erlandsen draws the attention to the marked autoxidability characteristic of cuorine. As the autoxidable substances are generally considered strictly necessary to the vital processes, and as the organism exacts a far more continuous and relatively far greater work from the heart than from the other muscles, the existence in the heart (and in the heart only) of an eminently autoxidable substance like cuorine may have a deeper meaning. Remembering the importance ascribed by the most competent authorities to the lecithinoid substances in the explanation of the effects on the body of many drugs, *e.g.* the hypnotics, one awaits with interest further researches on this point. A pity it is that these researches are so exceedingly difficult.

Prof. Thorkild Rovsing has published a paper of the highest importance on his experience during the last sixteen years with vesical tuberculosis. During this time he has treated fifty-six cases of the disease and has cured twenty-five of them, while eight more were improved. As vesical tuberculosis was reputed incurable till only a few years ago, Rovsing's conclusions, given below, are possessed of great interest. Vesical tuberculosis is, as a rule, propagated from a primary renal tuberculosis. Only exceptionally does a primary genital tuberculosis spread to the bladder, and more rarely yet the bladder itself is the first and only organ affected. It is hopeless to treat a vesical tuberculosis propagated from the kidney before the diseased kidney has been removed. Therefore one should never acquiesce in the diagnosis of cystitis tuberculosa, but should try by all means to establish the state of the kidneys, whether they are healthy or whether one or both kidneys are suffering. This must be ascertained by catheterization of the ureters and not by cystoscopy alone, or by the use of segregators, as the cases of the author show that an erroneous diagnosis often will be made if the latter methods are adhered to. Even if the urine from both ureters contains tuberculosis bacilli, it is not certain that both kidneys are suffering from tuberculosis, as the cases of the author show that vesical tuberculosis may ascend through the ureter a shorter or longer distance toward the healthy kidney. Then the urine passed through this ureter becomes purulent and contains bacilli, though the kidney itself is healthy. In these cases, as also in those where ureteral catheterization is impossible, owing to ulcerations of the bladder or stricture of the ureteral orifices, a double exploratory lumbar incision, eventually with ureterostomy in order to diagnose ascending ureteral tuberculosis, can give the information of the state of the kidneys necessary to the selection of the proper treatment.

After the removal of the (primarily) affected kidney, a coexisting beginning or not too widespread vesical tuberculosis not seldom heals without further treatmnet, as the author was the first to observe twelve years ago, and has till now observed in ten cases. If, after the removal of the diseased kidney, the vesical tuberculosis spreads further or has already affected large areas of the bladder, the treatment originated by the author, viz., vesical injections of a 6 per cent. aqueous solution of carbolic acid, will cure the great majority of cases treated by it (thirteen cases cured by the author).

Dr. P. Kuhn Faber has successfully treated with *x*-rays a bad case of neuralgia of the third trigeminus branch. The beginning of the neuralgia dated four years back. Resection of the nervus alveolaris inferior was performed and paraffin poured into the alveolar canal, in order to prevent the two nerve-ends from growing together. After the operation the patient felt no pain for four months. Repeated resection of the mandibular nerve just before it enters the canal brought about a new relief of six months, but then the neuralgia again set in and deprived the patient totally of sleep for weeks together. After five treatments by the *x*-rays the neuralgias ceased and have not reappeared for some months.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 6, 1906.

Appendicostomy and Cecostomy for the Relief of Chronic Diarrhea.—Nine cases are detailed by S. S. Gant, eight being of the former and one of the latter procedure mentioned in the title. After certain general remarks as to the nature of chronic diarrhea, he refers briefly to the work of various men along this line, and describes his own technical methods in the following words: The abdomen is opened by a short intermuscular or gridiron incision such as is made for appendectomy. The appendix is located, freed if adherent, brought outside the abdomen, opened, and a probe inserted to make sure of its patency. If found to be too short, strictured, or otherwise unsuitable, it should be removed and a cecostomy substituted. If, however, the appendix is sufficiently long and patent, it is ligated and cauterized. The cecum at its base is sutured to the abdominal wall and the parietal peritoneum, muscles, and skin closed with plain catgut sutures. The appendix is anchored to the skin by one or two sutures and the wound covered with protective tissue and gauze, held in place by adhesive plaster. In some cases the mesoappendix was left intact, while in others the artery was ligated and the peritoneum stripped off, but apparently neither method had any advantage over the other. Usually the part of the appendix external to the ligature sloughed about the fourth or fifth day, leaving the open stump projecting about one-fourth of an inch above the skin. The irrigations are begun immediately, using saline solution, ice water, or solutions of boracic acid, potassium permanganate, carbolic acid, krameria, ichthyol, bichloride of mercury, or nitrate of silver. In practically all cases the abdominal discomfort and frequent evacuations ceased immediately after the operation or after the first irrigation, and within a few days the stools became almost normal, containing but little blood or mucus. It appears to make but very little difference what irrigating fluid is employed, provided that it is used daily and in sufficient quantity to thoroughly cleanse the bowel. No untoward effect has followed the operation in the author's hands except that stitch abscesses occurred in two or three cases.

New York Medical Journal, September 8, 1906.

The X-Ray in Splenic Enlargements.—C. Eastmond reports one case, though two others have been treated with a like result, but no account was kept of the white cell counts. In the case detailed the blood condition improved markedly, while the general strength increased. At the end of six weeks, however, the spleen itself had shown but little change. The use of a harder tube and with much greater power and shorter exposure, led to a rapid diminution in the size of this organ. The author speaks of the result as a "symptomatic" cure only, and he admits that most, if not all, of these cases relapse sooner or later. He says that it is now generally agreed among radiotherapeutists that the *x*-ray tube emits two sets of rays, soft and hard, the former acting upon the skin and superficial structures, the latter upon the deeper. To affect the spleen, a preponderance of hard rays is necessary, and the fewer the soft ones the better, for there will be less action and reaction upon the skin. To obtain these hard ravs one must use an old tube of high vacuum. The current usually used is not sufficient to excite such a tube, and if the vacuum is reduced to the point where a light current will excite it (the usual procedure), the resulting rays will be too soft to penetrate to the spleen.

Deep Breathing as a Therapeutical and Preventive Measure in Certain Diseases of the Lungs.—J. H. Pryor considers deep breathing as a valuable measure, and deplores the scanty attention paid to it in current teaching. It serves as a preventive measure in small and deformed chests, with insufficient or restricted respiratory capacity. The deformities due to rickets and spinal curvature are often susceptible of great improvement by combined exercises of the lungs and special gymnastics. Another group of cases comprise the results of acute or chronic diseases of the lungs and pleuræ, such as prolonged or delayed consolidation with incomplete resolution, partial consolidation and collapse, bronchiectasis, and fettering pleuritic adhesions. Under all these circumstances, the respiratory capacity is diminished, the play of the lung is limited, ventilation is inadequate, and chronic changes take place in the form of interstitial proliferation, bronchiectases, phythisis, and collapse. The patient complains of shortness of breath, dyspnea on exertion, palpitation, weariness, and pain over the side affected. The latter symptom is often more pronounced in cold weather. Neuralgia of the intercostal or subscapular nerves may come on. Now, under all these conditions, deep breathing exercises relieve the condition by removing the cause. Pryor doubts whether any lasting benefit is derived in cases of acute or advanced cases of true tuberculosis, though he believes that the dangers of infection and hemorrhages in such cases from deep breathing are greatly exaggerated, and he bases this opinion on his personal experience. Probably one of the chief reasons why high altitudes have proved beneficial is to be found in the compulsory increase of respiratory activities. Finally, says the author, breathing exercises must be taught and watched to be effective. Each case must be considered in itself, and the kind and degree of breathing exercises required be carefully selected.

Diagnosis of Gastric Ulcer.—H. Weinstein says that an untreated ulcer may result in one of the three following conditions: (1) Severe hemorrhage by rupture of a vessel in the stomach wall. (2) The serosa becoming involved in the ulcerative process may rupture, or, if adhesions to neighboring organs are present, an encapsulated abscess will ensue. (3) Frequently the ulcer extends both laterally and in depth, presenting a funnel-shaped, terraced appearance, and it may attain the size of the palm of the hand The mere healing of a chronic ulcer is no satisfactory cure, for the consequent cicatrices may deform the stomach or cause atrophy of the glandular elements. In a case of ulcer one may find at first only painful pressure after a large meal. Even this may disappear if the patient takes only a liquid diet. At this stage careful inquiry will disclose the fact that the pain in the epigastrium or back appears, or, if constant, is aggravated after a meal. Physical examination will elicit an epigastric or dorsal pain point, or both. If in addition to the foregoing, which, by the way, are the most reliable symptoms of ulcer, there are evidences of hyperacidity as expressed in acid eructations, vomiting of sour material, headaches, and constipation, then we may safely conclude that the case before us is one of ulcer, and we should lose no time in instituting appropriate treatment. It is not necessary to wait for hematemesis to confirm the diagnosis, and we may rest assured that sooner or later this positive symptom will appear if we but wait for it. Hematemesis occurs in about one-third of the cases of ulcer, but it is almost always a late symptom and therefore preventable. Absence of hemorrhage is usually the cause of failure to diagnosticate ulcer.

The Relation of the Physician to Sanitation and Hygiene.—H. P. Sights believes that physicians should be more careful than they usually are to instruct their patients as to many things which medical science has proven —such as the agency of the common house-fly in the transmission of disease. They should take a more decided stand as to the right of the people to a healthful atmosphere and good water. Cordial support should be given to all Health Departments in their efforts to stamp out contagious diseases. The lessons of moral prophylaxis, etc., should be impressed on all our college students. Gonorrhea should not be looked on as merely a matter of hard luck to the sufferer, but shown up to be the forerunner of stricture, prostatic disease, rheumatism, and uterine and various pelvic troubles. Many foolish notions exist among the laity as to bacteria and their mode of action. The truth must be taught. Patients who have pulmonary tuberculosis should be told they have it, so that they can properly care for themselves. Finally, physicians should be absolutely truthful when certifying as to the cause of death in any case.

Berliner klinische Wochenschrift, August 27, 1906

A Simple Method of Demonstrating the Presence of Carbonic Oxide in the Blood.—Horoszkiewicz and Marx, in the course of their investigations on the hemoglobin derivatives formed in blood that has been subjected to the action of quinine, hit upon the following test for the presence of carbon monoxide in blood. The specimen to be examined is mixed with an 8 per cent. solution of hydrochlorate of quinine in the proportion of 2 c.c. of blood to 4 c.c. of the quinine solution. This mixture is gently heated in the Bunsen flame until it has boiled up once; after allowing it to cool slightly, two to three drops of perfectly fresh ammonium sulphide are added and the mixture is immediately well shaken. In the presece of carbonic oxide a clear red color results, while normal blood turns a dirty brownish-green. The change in color is said to be very striking and as the specimen keeps for weeks without change, the test is a particularly useful one in medicolegal work.

The Treatment of Lupus Vulgaris by a Combination of Resorcin and the X-Ray.—Reines speaks highly of a combined form of treatment for this affection, in which the disease foci are first denuded of epidermis by the application of 33 per cent. resorcin paste and then subjected to the x-ray, the theory being that by removing the superficial epithelial layers the rays are enabled to act directly on the diseased tissue with unabated potency. The paste is applied to an area not larger than the palm of the hand once daily for five or six days, at the end of which time it will be found possible with a bit of gauze or a curette to remove the superficial epithelium overlying the lesions, while the healthy skin will remain intact. The Roentgen rays are then applied and the sessions repeated at regular intervals, epidermization of the lesions being prevented by repetitions of the resorcin application as needed. In order to prevent too great irritation periods of rest under boracic ointment are given. The method is said to be particularly advantageous owing to the saving of time in treatment it effects.

Münchener medizinische Wochenschrift, August 21 and 28, 1906.

The Cultivation of Typhoid Bacilli on Bile.—Conradi calls attention to the shortcomings of the present methods for the early recognition of typhoid. Examination of the feces, for example, gives a positive result only in about one-quarter of the cases during the first week, while the Widal reaction becomes marked only during the second. Blood cultures seem to furnish the most reliable early test, although the method is not ordinarily applicable in practice. As bile is known to favor the growth of the typhoid bacilli, Conradi added a small quantity to the blood procured from the patient and then plated the mixture on agar. For convenience, ox bile is preserved in sterile glass tubes, into which the blood from a puncture in the lobe of the ear is allowed to flow, and then the tube may be sent to the laboratory. It has been successfully used in a large number of cases.

Hyperemia in the Treatment of Otitis.—Hasslauer has subjected a number of acute and chronic cases of ear suppuration to this method of treatment with good success. The chronic cases were not apparently benefited, unless an acute exacerbation had occurred. In several instances an unfavorable action must be attributed to the method, for a diffuse extension of the suppurative process took place into the external ear. In the acute cases better results were obtained, and in fourteen cases of pronounced otitis media. five were absolutely cured, absorption of the exudate taking place very rapidly. The procedure advocated by Keppler and Stenger was the one found most effective.

Alcohol and the Neuroses.—Loewenfeld contributes an extensive review of this subject, which leads him to the belief that alcoholism must be regarded as a highly important factor in the etiology of the functional diseases of the nervous system, and that it is of significance not only on account of the frequency of its action, but also on account of the gravity of the consequences induced by it. It may lead to neurasthenia, even in the absence of any predisposition; it may evoke epilepsy in those who inherit a tendency to the disease, and it may greatly increase the severity of the malady when already present. It may greatly aggravate a hysterical constitution, and induce acute outbreaks of mild or severe hysteria, and may also exert a very unfavorable effect on other types of the neuroses. Furthermore, all of these disorders possess in common the property of predisposing to alcoholic excess, and one does not need to be an advocate of total abstinence to realize that in all functional nervous diseases it is advantageous for the patient to refrain entirely from the use of alcoholic beverages. While even small amounts of alcohol may be decidedly injurious to epileptics, it is not necessary to be quite so strict in cases of hysteria and some forms of neurasthenia. Although in such cases some concessions may be made to the patient's inclination, as a rule it is desirable to avoid the habitual use of alcohol even in moderation in all cases of functional nervous disorders, and it appears highly undesirable to com-

plicate the therapeutic problem in these diseases, which are supposed to depend largely on some toxic action, by the continual introduction into the body of another toxic agent, such as alcohol.

The Course of the Intramuscular Nerve Trunks and Its Significance in Plastic Operations on the Muscles.—Wollenberg endeavors to explain the irregularities observed in the results of operations in which muscle transplantation is resorted to, by a study of the course of the nerve fibers in the larger muscles. Microscopical studies show that the nerve trunks for the most part follow the course of the blood-vessels, and by injecting these with mercury and then making radiographs, the author was enabled to demonstrate that in most muscles, except a very few, such as the gracilis, the semitendinosus, the gastrocnemius, and perhaps also the peronei and the tibilias anticus, the course of the vessels and therefore of the nerve filaments is transverse, rather than parallel to their long axes. In making muscular flaps it is apparent, therefore, that there is great likelihood of cutting enough of these transverse branches to render it very unlikely that the flap will retain the power of independent control. The practical conclusions drawn by the author are that in such operations the flap must not be too narrow, and the split must not extend higher than about the middle of the muscular belly. Small muscle flaps can be used only in dealing with those muscles that have longitudinal nerve trunks.

The Curability and Treatment of Tuberculous Meningitis.—Reibold says that so far four cases of what appears with reasonable certainty to have been tuberculous meningitis have been reported, in which recovery followed. To these he adds a fifth, in which he thinks the favorable outcome was brought about by persistent resort to spinal puncture. The patient was a girl of sixteen years, and in all 574 c.c. of cerebrospinal fluid were withdrawn at twenty-four punctures, which at first were repeated at daily intervals and later on less frequently. The author believes that the beneficial effect of the therapeutic measure was very evident in this case, and urges that it be more frequently resorted to. He considers that the spinal canal should be punctured at least once a day as long as the pressure exceeds 25 to 30 c.c. of water, and the amount flowing out at a final pressure of 10 to 12 c.c. equals 25 to 30 c.c. or more.

Deutsche medizinische Wochenschrift, August 23 and 30, 1906.

The Relation of the Diplococcus Intracellularis Meningitides to the Gonococcus.—Ruppel publishes the results of his recent experiments, by which he succeeded in cultivating the meningococcus in a fluid medium after repeated failures. It was also possible to produce the characteristic disease in animals by inoculation, and then to obtain the organism again in pure culture from the pleuritic exudates, the blood, and the cerebrospinal fluid. These strains were also found to be very virulent, which would serve as a means of testing the immunizing sera as regards their potency. Horses inoculated with the virulent cultures were found to produce a serum which had a high protective value in mice. The relation between the meningococcus and the gonococcus is believed by the writer to be very close, and it is probable that by analogous culture methods an antigonococci serum may likewise be produced. He thinks that the differences between the sera are merely quantitative.

The Therapeutic Effects of Antistreptococcus Serum.—Aronson contends again that the unfavorable results following the use of the antistreptococcus sera are due to the indiscriminate employment of the method without preliminary bacteriological cultures. Zangenmeister used the serum in several cases of septic infection after operation for carcinoma, and condemned it as useless. Aronson shows, however, that in order for the serum in question to become effective it is necessary that the leucocyte production be preserved intact, so that the cocci may be taken up and rendered innocuous. This property is not present in a condition of systemic intoxication, such as that associated with the active growth of carcinoma. Aronson is doubtful whether even an active immunization would be efficient in such cases.

Death Through Suffocation Caused by a Necrotic Bronchial Gland.—Reunert says that some instances of reported thymus death, in which no autopsy was made to confirm the diagnosis, may not improbably have been the result of other causes. He describes one instance of sudden death in a child which was the result of suffocation caused by plugging of the trachea by a mass of necrotic material, resulting from the breaking down of a tuberculous bronchial gland. The patient was a boy two and one-half years old, who died suddenly shortly after having been put to bed. At the autopsy the pharynx and larynx were found to be normal, but in the trachea, just below the crycoid cartilage, was a soft, cheesy mass, completely occluding the lumen of the tube, and in the right bronchus, near the bifurcation, there was a perforation leading into a cavity containing cheesy bronchial nodes. The left lung was normal, but the middle and lower lobes of the right lung were tuberculous. Death was evidently the result of the occlusion of the trachea by the mass of necrotic tissue, which the child had been unable to expel.

Ocular Palsies Following Spinal Anesthesia.—Mühsam says that three cases have already been reported, in which paralysis of the external muscles of the eye has followed the induction of spinal anesthesia. He adds to the list two cases which have come under his own observation. The first patient was a man of twenty-six years, who on the tenth day after spinal anesthesia developed a typical right-sided abducens paralysis, which had disappeared again entirely twenty-one days later. The second patient was a woman of twenty-seven years, in whom right-sided abducens paralysis appeared on the fourth day after operation, and persisted for twenty-two days. In both of these cases diplopia was very marked. In another communication, Lang describes two more similar cases; one in a man of sixty-one years and the other in a man of forty-one years. In the first case the ocular weakness appeared on the eleventh day, the right abducens being involved. The other patient suffered from a left-sided abducens paralysis, which appeared on the eleventh day and disappeared on the sixteenth day. The condition still persists, though in diminished degree, in the older patient.

The Treatment of Pulmonary Tuberculosis by Means of Artificial Pneumothorax.—Forlanini says that in the past ten years he has treated twenty-five cases of pulmonary tuberculosis by the induction of artificial pneumothorax, brought about by the injection of nitrogen into the pleural cavity. The results he considers have been very satisfactory, and a number of histories are given in which cure was apparently effected. The underlying principle is the complete immobility secured for the affected lung, and the collapse of all its cavities. Essentials in carrying out the treatment are to have the pneumothorax extensive enough to maintain complete immobility of the lung, to induce the pneumothorax very gradually by the daily introduction of very small amounts of gas, and to maintain a constant pressure in the pleural cavity. The author has devised a special apparatus for this purpose, which is described and figured.

French and Italian Journals.

Hysterical Hematemesis.—Mathieu and J.-Ch. Roux admit the possibility of hysterical hemorrhages of the stomach. These authorities speak of three classes in which hysteria by itself seems to explain hemorrhage without previous ulceration. The first class, or mucous hemorrhage, is an esophageal vomiting, tinted red by a small quantity of blood. The patient feels a sensation of suffocation and suddenly ejects from about forty to sixty grams of bloody liquid. This liquid looks like currant juice diluted with water. As to the pathogenesis, it is probably due to a bloody salivation or to a slight esophageal hemorrhage. The second class is rare and is called hysterical hematemesis coexistent with multiple hemorrhages of nervous origin. The history of a young hysterical woman is reported, who suffered from repeated attacks of hematemesis and hemorrhage from the left ear, without the slightest appreciable lesion of the skin. The third class includes patients who suffer from a sudden attack of hysterical hematemesis, but who neither before nor after show any sign of dyspepsia.—*Revue Française de Médecine et de Chirurgie*, June 25, 1906.

Tobacco and the Auditory Function.—Luigi Chierici states that, although there is no drug that gives more pleasant sensations than tobacco, still we must acknowledge that consumers of tobacco, as well as those who work in it, are subject to alterations of the auditory functions, due to pathological conditions of the middle and internal ear. The middle ear complications are of inflammatory nature, due to the extension of diseases of the pharynx, a result of the irritation of the ammonia that is produced in the process of burning of the tobacco, as well as of some of the alkaloids contained in the drug. There are nine alkaloids in tobacco, several of which are poisonous. Nicotine produces a dehydration of the tissues which irritates the nasopharynx, and the use of tobacco is one of the commonest causes of chronic nasopharyngitis. The ammonia irritates the conjunctiva and the olfactory nerve, as is shown by lacrymation and sneezing. Catarrhal auditory symptoms due to tobacco are vertigo, noises in the ears, and loss of hearing. Lack of hearing is also produced by secondary lesions of the auditory nerve. These are probably due to vasomotor changes due to nicotine, which causes vasoconstriction, resulting in anemia of the auditory nerve, and when continued this results in loss of hearing.—*Gazzetta Medica di Roma*, June 15, 1906.

Book Reviews.

Walter Reed and Yellow Fever. By Howard A. Kelly, Professor of Gynecological Surgery, Johns Hopkins University. New York: McClure, Phillips and Company, 1906.

By this timely volume Dr. Kelly places under obligation to himself both the medical profession and all who are interested in scientific progress. The book is a biography of Reed and also a historical and scientific account of yellow fever, its ravages in the past, modern work on the subject, and a description of the relation between the mosquito and the spread of yellow fever. The whole book is written in plain and straightforward language, controversy and technical discussions being omitted. The author rightly emphasizes Reed's services to the world, and at the same time draws attention to the fact that appreciation of Reed's great work has been slow and inadequate. The author says: "The inspiration of Reed's life lies to me in the fact that, though a man of war, he ravaged no distant lands, he destroyed no tens of thousands to make his reputation, but by quiet methods, when there was no strife, he saved countless lives and swept away a hideous plague, which from time immemorial had periodically visited our shores, devastated our fair land, and too often snatched from the years of peace and plenty all their blessings." A chapter is devoted to the work of the other members of the Yellow Fever Commission of 1900, viz., Carroll, Lazear, and Agramonte. Every physician should read this interesting volume and pass it on to patients and friends: it is historical, scientific, and patriotic.

Problems in Animal Metabolism. A Course of Lectures Given in the Physiological Laboratory of the London University at South Kensington in the Summer Term, 1904. By J. B. Leathes, Lecturer on Physiology in the Medical School of St. Thomas's Hospital. Philadelphia: P. Blakiston's Son and Company, 1906.

The increasing interest in the study of biochemistry that has characterized recent years has led to the appearance of many volumes on this subject, so that there is now no scarcity of books devoted to it. The present series of lectures, or perhaps more properly essays, forms a highly suggestive disquisition on some of the more intricate aspects of metabolic activity, the author's object being to point out that the study of animal metabolism is daily becoming less the study of the sum total of chemical change in the body, and more the study of the individual chemical reactions, the items that go to form the final sum. The lectures have the following titles: Introductory, Physiological Chemistry and Metabolism; The Assimilation and Synthesis of Carbohydrates; The Catabolism of Carbohydrates; The Assimilation and Synthesis of Fat; The Catabolism of Fat; The Assimilation and Synthesis of Proteids; The Catabolism of Proteids; The Metabolism of Cyclic Formations.

Infection, Immunity, and Serum Therapy. In Relation to the Infectious Diseases Which Attack Man; with Considerations of the Allied Subjects of Agglutination, Precipitation, Hemolysis, etc. By H. T. Ricketts, M.D., Instructor in Pathology, University of Chicago. Chicago: American Medical Association Press, 1906.

The lore of immunity and its allied subjects is still—and apparently is destined for some time to remain—in so complicated a state that the average medical reader finds it difficult to orient himself satisfactorily in this comparatively new field of investigation. So far our knowledge consists for the most part of a formidable mass of individual observations which have been ingeniously incorporated in a web of fine-spun theories whose ultimate fate is still uncertain. Most of this work has been published in special journals not readily accessible, and authoritative résumés of what has been accomplished are therefore highly desirable. The recently published English versions of Metchnikoff's "Immunity in Infective Diseases" and Ehrlich's "Collected Studies on Immunity" are well calculated to serve in this capacity, but suffer to a certain extent, from the standpoint of the general reader at least, in that they present the necessarily somewhat biased views of the leaders of two different schools, whose tenets, though not wholly incompatible, are not altogether easy to reconcile. The present volume is an admirably judicious conspectus of the whole field, in which the complicated terminology of the subject is made clear, the various theories are considered in detail, and their practical application is set forth. In the first part, devoted to general considerations, the underlying principles of natural and acquired immunity, toxin and antitoxin formation, the phenomena of agglutination and of precipitin formation, phagocytosis and its relations to the side chain theory, serum therapy, etc., are discussed. In the second part the application of these considerations to special diseases is taken up and separate sections are given to each of the infectious disorders, including diseases of doubtful etiology. An appendix brings the text well up to date, and a short but useful bibliography as well as an excellent index contributes to the value of the work. The volume is much more than a mere compilation, for the author's own personality is prominent on every page and his critical commentaries are always well advised. It is a pleasure to commend what is undoubtedly the most complete exposition of this subject at present available in English.

Notes on Surgery for Nurses. By Joseph Bell, M.D., F.R.C.S. Edin., Consulting Surgeon to the Royal Infirmary and to the Royal Edinburgh Hospital for Sick Children. Sixth Edition, Thoroughly Revised. New York: William Wood and Company, 1906.

This is one of the best instruction books for nurses that it has been our privilege to see. It is written in the lecture or conversational style and contains the substance of the lectures which the author has been delivering to the nursing staff of the Edinburgh Royal Infirmary for the past quarter of a century. All the subjects which concern nursing in surgical cases are taken up and treated briefly, but clearly and interestingly. Not the least useful of the lectures is the final one, containing "general advice to nurses"; the hints and the dont's and the practical advice herein contained may well be taken to heart by all young women about to enter the nursing profession.

A Nurse's Hand-Book of Medicine. By J. Norman Henry, M.D., Clinical Professor of Medicine, Woman's Medical College of Pennsylvania; Assistant Physician, Philadelphia Hospital; Physician to Out-Patient Department and Lecturer to Nurses, Pennsylvania Hospital. Philadelphia and London: J. B. Lippincott Company, 1906.

This most practical book of instruction to nurses comprises the substance of the course of lectures delivered annually by the author to the class of nurses at the Pennsylvania Hospital. In these days a trained nurse must not only know how to take the temperature and pulse of her patient, to measure the doses of medicine prescribed by the physician, and to make her charge as comfortable as may be; she must also be trained to know the symptoms of his disease and to be alert to detect any signs of good or evil omen which may declare themselves in the intervals of the physician's visits. She must be the physician's assistant, not his servant, and to fulfil this rôle satisfactorily she must have a medical training. To this end, in all good training schools a course of lectures is given by some member of the hospital staff, but in addition to the lectures a course of reading is necessary. For this there is no better book, so far as the purely medical side is concerned, than the one before us. The author has happily avoided the fault of speaking above his audience, and his lectures are adapted to the comprehension of readers who are not grounded in all the details of anatomy, physiology, and pathology. The student nurse who will study this book, supplementing it with one on surgical nursing, such as the "Notes on Surgery for Nurses," reviewed in the present issue, and one on obstetric nursing, will be well fitted for the work that is before her.

New Serum-Therapy. By D. Montgomery Paton, L.R.C.S. and L.R.C.P. Edin. New York: William Wood and Company, 1906.

This little volume contains the results of several years' experience, on the part of the author, with serum therapy. The book may be roughly divided into three parts, the first being more or less introductory and at the same time referring to unsatisfactory results with serum therapy, which may be due to either the serum, the patient, or the physician. The second part, which forms the bulk of the book, is the report of several series of cases in which the serum therapy was tried. These cases include almost every kind of possible ailment, and for purposes of reference are arranged alphabetically, extending from appendicitis to traumata. The third part deals with the theory of the action of the sera orally administered; tissue resistance and immunity are also discussed in this part. The action of the sera when administered by the mouth is explained on the theory of increased tissue resistance and is regarded as being neither antitoxic nor antibacterial. The book, which represents considerable work on the part of the author, is clearly and concisely written, and is well worth reading. While there are reports of nearly three hundred cases treated by the method here advocated, no extravagant claims are made for the new serum therapy, the author's conclusion being that while serum therapy has been of great service it has not fulfilled the bright hopes of its inception.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-first Annual Meeting, Held at Hot Springs, Virginia, May 22, 23, and 24, 1906.

The President, Dr. Richard B. Maury of Memphis, Tenn., in the Chair.

Is Gynecology Dead? Or Gynecology Against Overdone and Misapplied Surgery.—Dr. E. C. Gehrung of St. Louis protested against unnecessary, if not criminal, surgery that had been and was still being practised in cases that could not be benefited by the knife, and in others that could be as well or better treated by other and less radical means. In many of these latter, the knife might obtain a quicker and perhaps just as good result, yet at the cost of mutilation. Many women complained of various kinds and degrees of suffering, yet a most careful examination did not disclose anything on which to operate. Such women might be treated gynecologically with good results. All uterine displacements should be considered in the light of ptoses and herniæ. These enteroptoses might be of minor degree only, or might extend to the kidney or other abdominal organs, and thus produce symptoms for which the simple uterine displacement would not account satisfactorily. Concerning forward displacements, the situation was altogether different. Since anatomists said that anteversion and anteflexion were the normal positions of the womb, the pathologist denied pathological effects to antedisplacements, and the practitioner was only too happy to ignore a state of affairs for which the means of relief were so imperfect apparently and so difficult to apply, with so little or no results in prospect. The wearing of a pessary he considered as much a cure as the wearing of a cicatrix.

Dr. George M. Edebohls of New York said that his views in regard to anteversion and anteflexion of the uterus had undergone radical changes since he began to practise gynecology. Whenever he found on examination that the uterus was anteverted or anteflexed, it led him to suspect that he had to deal with excessive mobility of the uterus; in other words, it was the therapeutic equivalent of retroversion of the uterus, and he treated it like a case of retroversion, where the uterus was flexible or nonattached, by shortening the round ligaments, and invariably his efforts had been crowned with success.

Dr. J. Riddle Goffe of New York expressed himself as having been convinced for many years that anteversion was a normal position of the uterus, and he taught that anteversion should be stricken out of the list of pathological positions of the fundus of the uterus. He had not found in later years any occasion whatever to interfere with a fundus that lay well to the front. He believed the symptoms of which patients complained could be accounted for by other conditions than the position of the fundus, and he invariably found some pathological condition to account for the symptoms. As to anteflexion, he regarded it in a different light, and believed that the anteflexed uterus was, as a rule, unless the flexion was acquired, an undeveloped uterus, and he treated it by improving its nutrition, stimulating its circulation, and developing the organ. If the case was one of acquired anteflexion, he treated it very much in the same way, but did not interfere with it surgically by shortening its ligaments or by attaching the fundus to abnormal tissue.

Enteroptosis.—Dr. Richard R. Smith of Grand Rapids, Mich., discussed this subject with special reference to body form, and the mechanical conditions governing the position of the abdominal organs, as well as the use of the *x*-ray in demonstrating stomach and intestines. He said that the subject was of especial importance to the gynecologist since the majority of the patients that came to him for relief showed more or less signs of this condition. It might form merely the background of the picture which the physician had before him, or it might be the complete picture without other pathology. It could be left out of consideration as far as treatment went in patients presenting neoplasms or pelvic inflammatory diseases. It was of great importance in considering lacerations, the various displacements of the uterus, as well as that large class of patients presenting pelvic symptoms, so called, with slight or undemonstrable lesion. One should consider the matter of operation in such cases with great care, and be most guarded in his prognosis. Above all, in case operation was done, it was very necessary that a proper course of treatment be carried out afterwards if one expected to get results. Enteroptosis and fair health were not incompatible. The treatment of enteroptosis should really begin in childhood, and it meant all that proper hygiene could do for children. If a woman came suffering from the symptoms which accompanied enteroptosis, she should be put to bed. She should have an abundant, easily digested diet, be massaged, and any necessary indications as to the bowels and digestion should be met. Pain usually decreased rapidly under this plan. He advised many of his patients practically as he would a patient suffering from tuberculosis. If the abdomen was prominent or very flabby, and the woman had general abdominal tenderness, and more especially if he found that by standing behind her and placing the hands over the lower abdomen (the patient standing) and lifting up, relief was obtained, he advised a well-fitting abdominal bandage. If the patient was young, the thorax more or less mobile, he had often given a system of breathing exercises with the idea of increasing the lung capacity and the size of the upper abdomen.

Dr. Charles P. Noble of Philadelphia thought it was a mistake to teach that all patients who had loose kidneys had enteroptosis. It was only in a minority of cases that a loose kidney was complicated with enteroptosis. Many patients who had enteroptosis had loose kidneys, but the converse, in his judgment, was not true. He had seen a few cases of loose kidney due to traumatism, but the number was very small. The great majority of women who had loose kidneys were unmarried; therefore the question of child-bearing was a very small factor in these subjects. He recalled three cases in which he had operated with satisfactory results.

Dr. Matthew D. Mann of Buffalo, N. Y., said the all-pervading style among civilized women of constricting the waist line was an important causal factor of enteroptosis. The universality of this mode of dress had a great deal to do with the condition mentioned, as it was more commonly found in women than in men. Men who wear tight belts, like blacksmiths, and men who constrict their waists with bands, were the subjects of enteroptosis. He condemned the use of corsets as worn by young women, and said the thorax could never attain its proper shape; the abdominal muscles lacked supportive power, and the contents of the abdomen would be forced down into an abnormal position. He had not been satisfied with operative procedures for the relief of the conditions mentioned.

Dr. John G. Clark of Philadelphia had had twenty-one cases of various ptoses of the viscera, chief among which were ptoses of the transverse colon, especially of the sigmoid flexure. He recalled several cases of ptosis of the sigmoid flexure, where a loop of bowel had been caught, in which there was alternating constipation and diarrhea, the patient going three or four or five days before the bowels would move, and then possibly suffering from a copious diarrhea. As to the etiology, his own feeling was that in many of these cases inattention to the bowels was one material factor.

Dr. J. Riddle Goffe asked what percentage of these cases came to operation.

Dr. Clark replied a very small percentage, as medical men relieved the great majority of them.

Dr. J. Clifton Edgar of New York called attention to the

too early getting up of women after confinement as a causal factor of enteroptoses. Women, when they got up too early after confinement, complained of stomach trouble, and drifted into the hands of a stomach specialist, who found dropping of the stomach or intestines, yet they had not complained before. Such women were prone to attribute their discomfort to uterine trouble, to uterine displacement, etc. Constipation, alternating with relaxation of the bowels, produced by the constant administration of cathartics given during pregnancy, was one of many causal factors. There was a faulty involution of the intestinal supports. As to prophylaxis, massage was a valuable means. He believed in women wearing an abdominal support for three months after confinement, especially primipara.

Dr. J. Riddle Goffe, in referring to the corset as a part of woman's dress, said he believed the new-fashioned straight-front corset was an improvement over those previously worn. He thought it was a beneficial garment to women. Instead of using abdominal supports, as was formerly his custom after laparotomy, he put a woman in a straight-front corset, which was carefully made by a woman who carried out his idea. He had also recommended this corset to be worn by women with pendulous abdomens. He reported two cases of gastroptosis which were relieved by operative procedures.

Dr. Smith, in closing, said a tight corset would exaggerate such conditions as he had referred to, but it must be remembered that enteroptosis was not due to the wearing of a tight corset nor to tight lacing. Enteroptosis was quite common in Arabian women.

Thrombosis and Embolism Following Abdominal Operation.—Dr. Joseph Taber Johnson of Washington, D. C., said that these complications occurred most frequently after supravaginal hysterectomies for fibroid tumors, although they might follow any abdominal section, notably after suspension of the uterus. The left leg was most frequently affected; both might be alternately. The symptoms generally appeared between the second and third weeks. Suppuration was rare. Recovery was the rule, although convalescence was protracted. Pulmonary, cardiac, or cerebral embolism might result, and prove rapidly fatal. The author reported two such cases. He gave the histories of six cases of thrombophlebitis with slow recoveries. Was this form of phlebitis the result of infection, or was the thrombus caused by an extension of the inflammatory process along veins injured during the operation?

Postoperative Embolism.—Dr. Eugene Boise of Grand Rapids, Mich., said that it affected the pulmonary artery and its branches in the great majority of cases. An embolus presupposes a thrombus. For the formation of a thrombus three elements were necessary, fibrinogen and calcium salts, which existed normally in the blood, and nucleoproteid, which was never found in normal blood. Nucleoproteid was formed by the degeneration of blood plates and leucocytes. Certain conditions of the blood and blood-vessels predisposed to thrombosis, as anemia or chlorosis, sepsis, excess of calcium salts, retardation of rate of blood current, traumatism, inflammation of coats of vessels, pressure, etc. Conditions calling for operation often involved one or more of these conditions. Fibroid tumors, which showed the greatest percentage of postoperative emboli, were coincident with excess of calcium salts in the blood and degeneration of the musculature of the heart, with consequent imperfect contractions, and residual blood, with retardation of blood flow, predisposing to heart clot. Indications for treatment were mostly looking toward prevention. When pulmonary embolism occurred, nothing was of much avail except the administration of oxygen.

Dr. Charles P. Noble said of 7,130 women operated on in the Johns Hopkins Hospital, in 48 phlebitis occurred. He did not think sepsis had much to do with the production of phlebitis or embolism.

Dr. Reuben Peterson of Ann Arbor, Mich., said that the mystery in the etiology of thrombosis and embolism made it doubly interesting. These conditions came on not only immediately after operation, but a month or six weeks afterwards. He had a patient in the University Hospital with an aggravated form of femoral thrombophlebitis which appeared in the third week after operation. The operation consisted of removal of nonpurulent, nonadherent appendages. There was not enough sepsis connected with the case to warrant one in thinking that any such condition would develop. He had taken statistics from his clinic for the last four and a half years, but which did not include the case mentioned. Of 3,000 operations performed during this period, at the University Hospital Clinic, there were six cases of femoral thrombosis. There were 1,050 women operated on. As regarded the time of its occurrence after operation, in one case it occurred eleven days after operation, in two cases fourteen days, in two cases nineteen days, and in one case twenty-one days.

Dr. Edward Reynolds of Boston said thrombosis had occurred most frequently in his experience in cases treated for the correction of retrodeviations of the uterus, in which there had been a great deal of congestion before operation. He was inclined to believe that thromboses were more frequent now than they were a dozen or fifteen years ago.

Dr. Andrew F. Currier of New York said the tendency of surgeons in these days to get patients up in a hurry after the performance of serious operations, had doubtless something to do with the production of thrombosis.

Dr. Seth C. Gordon of Portland, Me., agreed with Dr. Currier, and expressed the belief that too early getting up of patients after operation was causative of phlebitis.

Dr. T. J. Watkins of Chicago said evidence had been brought forth to show that thromboses were in some cases due to infection. Thromboses were common in infectious diseases, where there was no traumatism. They were common after typhoid fever. If statistics were worked up, he believed it would be found that thromboses were nearly as frequent after typhoid fever as after abdominal section.

Dr. J. Montgomery Baldy of Philadelphia said that, while sepsis, pressure by retractors, and traumatism of the pelvic veins were possible causal factors, none of the explanations so far offered seemed sufficient to explain a large number of cases. The subject was further discussed by Drs. Le Roy Broun, New York; John G. Clark, Philadelphia; M. Dührssen, Berlin, Germany; George M. Edebohls, New York; Richard R. Smith, Grand Rapids, Mich.; Richard C. Norris, Philadelphia; Henry P. Newman, Chicago, all of whom reported cases substantiating and corroborating the observations of both essayists.

Anomphalosis.—Dr. A. H. Buckmaster of Charlottesville, Va., read a paper on this subject.

Artificial Dilatation of the Cervix Uteri; Indications and Method.—Dr. George Tucker Harrison of New York said that, among indications for the artificial dilatation of the cervix might be cited in the first instance, local morbid conditions which interfered to such an extent with the dilatability of the os uteri and cervix that the natural forces were inadequate to the end to be attained. In addition, direct danger to mother and child might furnish an indication for the artificial dilatation of the cervix, a danger only to be averted by a speedy delivery of the child. An indication for the incision of the os uteri was given when immediate delivery was a matter of paramount importance, the os uteri not being sufficiently dilated, the cervical canal, on the contrary, unfolded. The deep incisions of the cervix usually combined with deep vaginal and perineal incisions opened up a wider field of operative intervention. The advantages of this procedure were pointed out. Mechanical dilatation of the cervical canal and external os uteri could be effected by distention with the fetal body after bringing down a foot; by the hand; by the use of expanding foreign bodies, such as tents, dilators, iodoform gauze, rubber bags, or balloons.

Dilatation of the Parturient Uterus.—Dr. Philander A. Harris of Paterson, N. J., in referring to manual dila-

tation, said he wished to be distinctly understood as referring to a method which he had employed for the past twenty-two years, and to no other method. By this method a far greater tonic strain could be applied upon the musculature of the cervical ring than by any other manual method. It relied mainly upon the flexor muscles of the fingers and hands. Not all cervices were dilatable. Cancer of the cervix might render it undilatable. A cervix which had been partly cut away, and amputated and sewn, or resewn, might contain so much white fibrous tissue that it was undilatable The average time required to dilate the cervical ring safely to a circumference of eleven or twelve inches should be forty-five minutes. If the cervix was not effaced, the average time of ninety minutes would be necessary to safely dilate the cervical ring to a circumference of eleven or twelve inches. The special advantage of knowing how to dilate the cervix manually was that the operator always had his hands with him, and they would scarcely ever fail to dilate the cervix if properly used. The advantages of instrumental dilatation, as accomplished by the instrument which the author presented, were that it would dilate any cervix that was dilatable. The instrument was easy of introduction. It did not have to be withdrawn and reintroduced over and over again, as would happen in the long operation, when done by the hand. It was provided with a dynamometer which showed not only the number of pounds pressure which was being exerted upon the cervical ring, but also whether the ring was dilating under the pressure. The instrument had a safety device, so that extensive laceration could not occur if it were properly used. A good deal of study was required to prepare one to use the instrument safely.

Advantages of Bimanual Dilatation of the Pregnant and Parturient Uterus.—Dr. J. Clifton Edgar of New York said that no method of manual dilatation could ever entirely supplant instrumental dilatation and incision. Dilatation by hydrostatic bags, the fingers of one or both hands, and branched dilators was feasible in most instances and was to be preferred to methods by incision. Incision of the uterus for purposes of dilatation was rarely indicated. The best method of cervical dilatation was the one which most closely imitated nature's method of dilatation; hence the advantages of hydrostatic and manual dilatation. He preferred the bimanual method of dilatation for the following reasons: "(1) The bimanual method is a closer imitation of the natural process than any other method of manual dilatation, being in this respect analogous to the bag of membranes or the hydrostatic bag, because the force used for dilating the cervical ring is directed from above downward. (2) Far greater force can be brought to bear upon the cervical ring, if need be, by the bimanual method than by any other, because the fingers of both hands are brought into play, and the stronger flexor muscles of the fingers and hand are the ones made use of. (3) There is no danger of prematurely rupturing the membranes, as there is when the fingers of one hand are passed through the cervix. (4) There is no interference with the original presentation or position, since the finger ends closely hug the lateral uterine wall; this cannot be said of any other manual method of dilatation, nor even by hydrostatic bags. (5) The bimanual method is far less fatiguing than any other method, because the strain is distributed in both hands, and the sense of touch of the operator's fingers is unimpaired, as there is no constriction of the hands as there is when one hand is used."

Dilatation versus Incision of the Gravid Uterus.—Dr. Egbert H. Grandin of New York, in a paper with this title, said the subject must be considered from the standpoint of elective operation and from the viewpoint of emergency operation. Incision should never be resorted to when the complication calling for intervention justified delay. Thus induction of labor in a case of pelvic contraction, interference in many cases of impending toxemia, as also in most instances of placenta previa, called for dilatation. On the other hand, the acute toxemias, the urgent instances of placenta previa, called for incision. The operative methods to be considered were abdominal and vaginal incision, and manual and instrumental dilatation. Broadly stated, in pelvic contraction, whenever it was doubtful that dilatation or vaginal incision would permit of delivery, abdominal incision was called for. In the acute toxemias, where the time element entered as a factor, and in rare acute cases of placenta previa, vaginal incision was justifiable; else dilatation should be the rule after a prescribed technique. Such devices as the Bossi dilator should receive the unqualified condemnation of American obstetricians. They were needless where the educated hand existed; they were dangerous under any condition. In the event of incision being indicated, the vaginal cesarean section was to be commended as preferable to the Dührssen incisions. The indication for either was extremely limited.

Vaginal Cesarean Section. — Professor Dührssen of Berlin, Germany, summed up the indications for this operation as follows: Vaginal cesarean section was indicated when in the case of an imperfectly dilated cervix, which would not permit of dilatation by gentler means, the life of the mother or the child was brought into danger. Also the presence of an operator experienced in vaginal operations was required. Imperfect dilatation of the cervix might be caused by pathological changes in the neighborhood of the lower uterine segment, or danger to the mother and child might arise when the pains had as yet caused insufficient opening of the os. In the first, the case was that of an absolute, while in the second, it was that of a relative, obstruction to delivery. The first must be removed because it would lead to danger for the mother and child. In the second, the danger was already present, and required the immediate emptying of the uterus. Among the special indications he mentioned that of eclampsia. He first established the principle that on account of the independent nature of eclampsia it was best, as soon as the diagnosis was made, to empty the uterus by narcosis. Investigations of the last few years, which recognized eclampsia as an intoxication produced by pregnancy, had shown that he was right. He had collected 376 cases of vaginal cesarean sections, with forty-eight deaths, a mortality of 12.7 per cent. This high mortality was not due to the dangers of the operation, but to the serious diseases for which operation was undertaken. This proved that the greater operation, namely, the radical vaginal cesarean section, had a lower mortality than the conservative vaginal cesarean section. Of 53 cases of extirpation of the uterus after vaginal cesarean section, this combination of operations, only five died. This further proved the low mortality of the conservative vaginal cesarean section, in clinics where immediate deliveries in cases of eclampsia had been effected according to the author's teachings and directions. Veit had only one death in 33 cases, Bumm only one death in his last 40 cases.

Development of Cancer in the Cervical Stump Following Supravaginal Hysterectomy.—Dr. Andrew F. Currier of New York said that the cases in which this complication might arise were usually those in which the uterus had been removed for myoma. That myoma frequently coexisted with cancer was a matter of common observation. Piquand had collected 45 such cases, in 24 of which it was thought that the fibromuscular elements had been transformed into epithelial cells, although in some of them there were preexisting cells which proliferated and developed malignancy. These cells were supposed either to have been derived from the embryonic remains of the Wolffian or Muellerian canal, or to be simply epithelial ingrowths into the fibrous tissue. The author was satisfied from his own experience that the coexistence of cancer and myoma was much more frequent than Piquand would seem to think. Noble, in an analysis of 1,188 cases of fibroid tumor operated upon by various surgeons, found 29 in which cancer of the corpus uteri was a complication, 12 in which there was cancer of the cervix, and 1 in which there was can-

cerous infiltration of a fibroid tumor arising from adenocarcinoma of the corpus uteri by metaplasia. The author had not yet seen any conclusive evidence that myoma was transformed into carcinoma, and histologically one would not expect such a sequence. The suggestions which occurred to him in connection with the consideration of this subject were the following: (1) The necessity of more careful clinical and pathological records, both public and private, in all the cases in which supravaginal hysterectomy was performed. This would probably result in the discovery of cancer of the endometrium in cases in which it was not suspected, and would probably bring to light additional facts in regard to the history of the evolution of cancer. (2) The periodical examination of those who have undergone the operation in question at not longer than six months' intervals. This was especially desirable for those whose tissues were in a bad condition of nutrition or who suffered from an hereditary taint. (3) Complete removal of the uterus offered greater security from cancer than retention of the cervix. If the patient's history revealed any conditions which suggested the possibility, near or remote, of future degeneration of tissues, complete extirpation should be the invariable rule.

The Search After Truth.—Dr. Richard B. Maury of Memphis took this as the title of the President's Address. He referred feelingly to the deaths of Drs. A. Palmer Dudley of New York, James R. Chadwick of Boston, Arthur W. Johnstone of Cincinnati, and R. Stansbury Sutton of Pittsburg, which had occurred during the year. The President then made some remarks on the subject of uterine displacements and referred to a discussion on anteflexion before the society in 1888, which was participated in by T. Gaillard Thomas, Graily Hewitt, Sir William Priestley, and others, the conclusion having been reached by those men at that time that the man who would not use pessaries in the treatment of anteflexion was unfit to practise gynecology. The intrauterine stem had passed out of the history of gynecology, perhaps forever, and would never again come into favor. The knowledge of pelvic inflammation was so fully disseminated that every practitioner realized the peril to a woman from its use. Dr. Maury discussed at considerable length how the uterus was sustained almost entirely by its ligaments, but said that some of the teachings regarding this matter were erroneous, in that the proper supports of the uterus were not the ligaments, but the various structures which constituted the two segments of the pelvic floor, as was demonstrated by Hart and Barbour. He discussed the various methods of the repair of injuries of the pelvic floor. In conclusion, he thanked the members for the distinguished honor conferred upon him in electing him President.

Results of Vaginal Section and Drainage in Early Cases of Ectopic Gestation.—Dr. Willis E. Ford of Utica, N. Y., reported twelve cases, which were all seen before rupture had occurred, and some of them as early as in the eighth week. In all the cases the incision was made cautiously into the sac, the finger being used to open into it, and the contents examined before the finger was wholly withdrawn, so as not to lose the landmarks. In no case was all the blood emptied at the time of the incision, but gauze was carefully passed into the opening and very firmly packed to prevent hemorrhage, and allowed to remain for a week before removal. In this way hemorrhage was avoided, and the operation was almost trivial in its consequences. The fact that the cases operated on by him early left almost no trace of anything wrong in the pelvis afterwards, and that the operation was so safe and so certain in its results, had impressed him that the society should urge early diagnosis and early operation in all cases of extrauterine pregnancy. If the teaching in the medical schools could be so modified as to impress upon medical students a more careful consideration of the subjective symptoms until skill enough had been acquired to enable the verification of the diagnosis to be made with certainty, he was sure that these cases of ectopic gestation would be seen early enough to be operated, and thus prevent rupture and hemorrhage in a large number of instances.

Review of the Surgery of the Female Pelvic Organs.—Dr. Seth C. Gordon of Portland, Me., presented the following conclusions: (1) That the Battey operation was one that did an immense amount of good in the practice of men of experience and skill in operating. The results in many cases were often delayed for obvious reasons. Undoubtedly much more harm than good was done because of inexperience in pathology and operative skill. (2) So-called conservative gynecology in too many instances was but a conservatism of diseased organs, in whole or in part, and not conservative of the health of the patient. (3) The sentiment was already changing from this extreme conservatism to a more careful consideration of the future condition of the patient, as instanced in a more general belief in hysterectomy for fibroids of the uterus instead of myomectomy. (4) In resections of the adnexæ regard should be paid to the history of the cause of infection rather than to the macroscopic condition, as the virulent germs produced changes that required total removal, together with the uterus, as the only safety to the patient. (5) In malignant disease of the uterus efforts should be made to discover it early, when panhysterectomy might be done to advantage. Advanced cancer might be treated tentatively by curettage and actual cautery. The extremely extensive operations of attempting removal of a wide margin around the uterus had produced unsatisfactory results, with a very high mortality and early recurrence. (6) Surgical measures for displacements were still *sub judice*, so far as any agreement as to any special method was concerned.

Conservative Operations on the Ovaries.—Dr. J. Montgomery Baldy of Philadelphia said, among other things, that sentiment had no place in deciding what should be done in the presence of a diseased ovary. Nor was the anatomical limit of disease and health in this organ the only thing to consider. It was difficult to tell what was and what was not disease in the ovary even microscopically, and in a very large number of instances it was necessary to decide the question by the symptoms and not by the make-up of the organ. Conservative operations on the ovaries were so commonly mixed up with the removal of adhesions, replacement of the uterus and other accompanying procedures, that it was utterly impossible to distinguish between results. Immediate results and end results were different. End results were not always reliable. It was only by the survey of the whole case, general as well as local, together with a profound practical knowledge of human nature, as well as a sublime respect for the vagaries of women's nerves, that one could appreciate the full truth. Again, end results were important in that large numbers of women were operated upon, the lesions corrected, and yet no good or only temporary results obtained. Cases were cited in point. Putting the facts squarely before the ordinary woman, giving her full, unprejudiced freedom of decision, in twenty-four cases out of twenty-five he believed she would decide for a complete operation. Sentiment existed largely in the doctor, not in the woman, and the few who were influenced by it had been educated up to that point by the class of doctor who objected to the removal of the ovaries because he found on analysis of a group of cases that "78 per cent. subsequently suffered a notable loss of memory; 60 per cent. were troubled with flashes of heat and vertigo; 50 per cent. became irritable, less patient, and some so changed as to give way to violent and irresponsible fits of temper; 42 per cent. suffered more or less from mental depression; 35 per cent. increased in weight, and some became abnormally fat," his general intelligence being such as not to appreciate that the picture he drew as one of bad results following faulty judgment was merely the symptoms of the natural and inevitable menopause and which would in a short time leave the woman as surely as they came to her.

Facts and Figures of End Results in One Hundred Cases of Conservative Operations on the Uterine Appendages.—Dr. Walter P. Manton of Detroit, Mich., said that in order to ascertain his own experience along conservative lines, he had taken one hundred cases from his notebooks. Of the 100 women, there were 30 single, 64 married, and 6 not noted. The following operations were done: On the ovaries, resection of both ovaries in 17 cases; right ovary in 26 cases; left ovary in 13 cases. Puncture of both ovaries in 22 cases; right ovary in 8 cases; left ovary in 14 cases. In 19 women the ovary of one side was found to be so largely involved as to require removal; the right in 6 instances; the left in 13. Resection was done in both tubes in 13 cases, right tube in 4 cases, and left tube in 9 cases. It was found necessary to remove one tube in 10 of the patients, the right in 4, and the left in 6 cases. The opposite side was left untouched or resected. In the 100 women the immediate results were entirely satisfactory; that is, all the patients recovered from operation and were relieved from the sufferings of which they formerly complained. The mortality was therefore *nil*, and the results temporarily perfect. The majority of these patients remained under observation for at least three months. He maintained that his own statistics and those of others showed that the conservative surgery of the ovaries and tubes, having passed the experimental stage, had established itself as a legitimate and successful operation in all the conditions to which it might be properly applied, and that it should be the operation of choice in all instances during the child-bearing age, where the diseased state of the organs admitted of its employment.

The Technique of the Repair of Large Vesical Fistulæ.—Dr. William S. Stone of New York read a paper on this subject, in which he summarized as follows: "(1) The basic principle in the repair of the large fistulæ is an extensive separation of the bladder walls, especially of the upper part in front of the cervix, by means of which it is readily sutured to the more fixed lower portion. (2) The uterus, which has been made movable by the free dissection entailed in the separation of the bladder, or by an additional incision posteriorly in some cases, is a most valuable supplement in filling up the opening in the vaginal wall. (3) With these principles applied, it is a matter of little importance what kind of suture material is used, or what relation the vesical and vaginal suture lines have to each other."

The Treatment of Vesicovaginal Fistulæ.—Dr. I. S. Stone of Washington, D. C., said experience had shown that wounds of the bladder made during the performance of surgical operations healed readily after careful application of sutures. This occurred after injuries at the base, as in vaginal hysterectomies, as well as in those at or near the fundus, which were comparatively frequent in operations upon the uterus for the removal of tumors. Two principal causes contributed to this result. One was the healthy condition of the bladder itself, and another was the ease with which the muscular wall of the organ could be approximated when absolutely free from the uterus or vaginal wall. It had been his experience that the very large fistulæ afforded such free drainage as to secure perfectly healthy mucous surfaces of both bladder and vagina, the only exception being in one bedridden patient who had been indifferently cared for and whose fistula was covered with incrustations. It would be found in many instances that large fistulæ had persisted because they were associated with injuries of the vagina of a serious character which produced extensive cicatricial contraction. He had found it unnecessary to treat these cases by the tedious method of Bozeman, and now felt confident that any fistula could be closed satisfactorily by first liberating the bladder from any adherent surface or organ which prevented its closure, and then by uniting the margins of the fistula with catgut, and afterwards, at the same sitting, by utilizing the vaginal wall of the uterus as might be needed to support the line of sutures in the bladder wall. This was opposed to the contention of those who favored suture of the supporting base only—the vaginal wall, for example. Finally, one might draw the vaginal walls forward after suitable dissection, or he might utilize the uterus as suggested by Kelly, which was done by drawing forward the cervix and making it secure with sutures to the anterior margins of the fistula, or by using the Freund method of turning the fundus downward and then forward into the opening. This last method seemed to him quite objectionable, as it necessitated a new opening into the cavity of the uterus to provide for the escape of the menstrual flow. He had overcome the disadvantages of this method of Kelly's, and had obtained abundant mobility by drawing down the uterus, cutting away the anterior vaginal wall, and dividing the broad ligaments so as to cause less traction upon the sutures. This had also been accomplished by separating the bladder from the uterus and broad ligaments through an abdominal incision, and by a division of the broad ligaments at their upper border, where they were attached to the uterus. This method had been used for the relief of fistula of any description, and the profession owed acknowledgment to Mackenrodt for priority and for clearly establishing its usefulness in almost any fistula of whatever shape, position, or size. In the treatment of small fistulæ, the vagina was divided longitudinally, the bladder separated from the vaginal wall, then united, and the vaginal wall closed, each independently. He had found its best and most useful application in the closure of large fistulæ, and where failure had resulted after previous attempts at cure. Illustrative cases were cited, in which excellent results were obtained.

Dr. Howard A. Kelly of Baltimore read a paper in which he discussed the abdominal extraperitoneal and abdominal transperitoneal operations. He pointed out the best means of exposing a difficult vaginal fistula; also how to preserve the uterus, and when to sacrifice it, if necessary. The methods of approximation in one layer or in two were also expatiated upon.

Shortening of the Round Ligaments Within the Inguinal Canals Through a Single Suprapubic Transverse or Median Longitudinal Incision.—Dr. Reuben Peterson of Ann Arbor, Mich., said that in his hands the Alexander operation for shortening the round ligaments had proved the most satisfactory of all the operations for backward displacement of the uterus. However, the operation had two great disadvantages. It was limited to freely movable uteri, and it necessitated two incisions. In the operation now employed by the writer the work (1) was performed through a single incision, preferably through a suprapubic, transverse incision not more than three inches in length. (2) The external rings were easily exposed by such an incision. (3) They could be readily, although not so easily, exposed by the ordinary median longitudinal incision. (4) The operation was applicable to adherent as well as movable uteri, since the abdomen was opened in every instance. (5) By following out a certain technique the round ligaments could be definitely and quickly located in every instance.

Dr. George M. Edebohls of New York reported a third case of renal decapsulation for puerperal eclampsia.

Hypernephroma Renis.—Dr. J. Wesley Bovee of Washington, D. C., reported two such cases and said that hypernephroma was the commonest form of kidney tumor. Many kidney tumors formerly thought to spring from kidney structure were now known to originate in islands of suprarenal tissue included in the kidney. He spoke of the so-called renal nests. Such deposits of renal tissue were common along the genitourinary tract, were usually benign in character, but might become malignant. The treatment consisted of removal when they gave symptoms.

Dr. George H. Noble of Atlanta, Ga., followed with a paper in which he discussed intramural abscess in the puerperal uterus.

Officers.—*President*, Dr. Clement Cleveland of New

York, *First Vice-President*, Dr. J. Clifton Edgar of New York; *Second Vice-President*, Dr. Willis E. Ford of Utica, N. Y.; *Secretary*, Dr. J. Riddle Goffe of New York (reelected); *Treasurer*, Dr. J. Montgomery Baldy of Philadelphia (reelected); *Member of the Council*, Dr. Richard D. Maury of Memphis, Tenn.

The society will hold its next annual meeting in Washington, D. C., 1907, in connection with the Congress of Physicians and Surgeons.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, June 11, 1906.

The Vice-President, Dr. Ransford E. Van Gieson, in the Chair

Lupulin in the Treatment of Gastrointestinal Diseases.—Dr. Heinrich Stern read this paper. (See page 443.)

Some Remarks on the Relations of the Gastrointestinal Tract to Nervous and Mental Diseases.—Dr. Robert Coleman Kemp read this paper. After briefly reviewing the relations of the gastrointestinal functions to toxemia, the writer stated he wished to call attention to the following propositions: (1) That epileptiform seizures or even true epilepsy might in some cases result from autoinfection; (2) that nervous, neurasthenic, or even melancholic symptoms might result from toxemia; (3) that in many cases of nervous or mental disease, derangements of the gastrointestinal functions, with resulting autoinfections, might aggravate the original condition from which the patient might be a sufferer, and thus create a vicious circle; (4) that it was the duty of physicians, both in asylum and private practice, to place their patients in the best possible physical condition. On a patient's admission to an institution for the insane, a thorough investigation should be made in each individual case into the existing conditions of the gastrointestinal tract, and appropriate treatment instituted. By this means alone could a scientific study of the relations of toxemia to nervous and mental diseases be made, and the results of treatment obtained. The late Dr. Emmet C. Dent was one of the first to appreciate the value of this method, and it had already been instituted at the Manhattan State Hospital on Ward's Island. Dr. Kemp said there seemed to be an unfortunate disposition on the part of neurologists to consider various gastrointestinal disorders invariably as the result of nervous or mental disease. While that was true in some cases, the speaker thought it had been fully demonstrated that in other cases the gastrointestinal disturbances were primary. All were familiar with the symptoms resulting from chronic constipation, such as headache, drowsiness, inability to concentrate the attention, general malaise, etc. Many nervous conditions, such as neurasthenia, mental depression, and melancholia, could be imputed to autointoxication. Autointoxication was common in alcoholism and drug habits. Epileptiform attacks were directly connected with putrefactive conditions in the intestines. Another interesting class of nervous cases resulting from autointoxication were those in which ptosis of the gastrointestinal tract was the primary factor. There were various types of this condition, from those of mild degree to the extreme condition described by Glenard. With descent of the stomach and intestines, there was a nephroptosis of the right kidney, sometimes of both, and there might be, in addition, ptosis of the liver and spleen. The gastric condition might be one of hyperchlorhydria, or of hypochlorhydria, or even achylia gastrica. Undoubtedly many cases of neurasthenia treated with brilliant results by the Weir Mitchell rest cure were the result of gastroptosis. Rest, and the putting on of fat to increase intraabdominal tension, were of value in ptosis. Rose's adhesive plaster belt was of service in the treatment of these cases, as it supported the organs and increased intraabdominal tension. The speaker said he considered mucous colic to be one of the manifestations of Glenard's disease, and the neurasthenic condition present in those cases to be the result of autoinfection. He also held the view that many cases of neurasthenia in women were due to autoinfection, associated with ptosis of the viscera. In closing, Dr. Kemp again emphasized the fact that the study of the relations of the gastrointestinal tract to nervous and mental diseases was of great importance.

Appendicostomy and Cecostomy for the Relief of Chronic Diarrhea: Report of Nine Cases.—Dr. Samuel G. Gant, in this paper, stated that chronic diarrhea was primarily the result of disease located in the colon, especially the sigmoid and rectum, very much more frequently than was supposed by the profession at large. The following were the pathological conditions of the lower bowel which most frequently gave rise to the condition: Carcinoma and other tumors within and without the bowel which obstructed its lumen; stricture; procidentia; invagination; polyps; fecal impaction; deviated coccyx; foreign bodies, colitis, and ulceration. Of these, the most common cause of the diarrhea was colitis, and the inflamed and ulcerated condition of the mucosa might be the result of a simple inflammation of the membrane, or it might be due to trauma, gonorrhea, syphilis, tuberculosis, or amebic dysentery, the latter proving quite common in this country since the recent war with Spain. When diet, internal medication, and irrigations had failed to arrest the progress of the disease, it was time to resort to such surgical procedures as colostomy, cecostomy, or appendicostomy. Dr. Gant said the object of his paper was to give his personal experience in the treatment of nine cases of persistent, ulcerative colitis and chronic diarrhea by means of appendicostomy or cecostomy. In eight of these cases the appendix was brought up, attached to the skin, and opened, in order to permit through-and-through irrigation. In the remaining case the cecum was opened and a catheter introduced after the method of Gibson, for the same purpose. The experience of Dr. Gant with these operations was most gratifying, and he said he had no more hesitation in advising these procedures for the relief of ulcerative colitis than he would of advising appendectomy for the relief of appendicitis. The operation of appendicostomy was comparatively simple; it could be quickly performed, and was no more dangerous than an interval operation for appendicitis. In performing this operation, the different operators varied the technique but little. The following, in brief, was the technique as practised by the writer: The abdomen was opened by a short intermuscular or gridiron incision, such as was made for appendectomy. The appendix was located, freed, if adherent, brought outside the abdomen, opened, and a probe inserted to make sure of its patency. If found to be too short, strictured, or otherwise unsuitable, it should be removed and a cecostomy substituted. If, however, the appendix was sufficiently long and patent, it was ligated and cauterized. The cecum at its base was sutured to the abdominal wall, and the parietal peritoneum, muscles, and skin closed with plain catgut sutures. The appendix was anchored to the skin by one or two sutures, and the wound covered with protective tissue and gauze, held in place by adhesive plaster. In some cases the mesoappendix was left intact, while in others the artery was ligated and the peritoneum stripped off. Usually the part of the appendix external to the ligature sloughed off about the fourth or fifth day, leaving the open stump projecting about one-fourth of an inch above the skin. The irrigations were begun immediately, using saline solution, ice water, or solutions of boracic acid, potassium permanganate, carbolic acid, krameria, ichthyol, bichloride of mercury, or nitrate of silver. In practically all the cases the abdominal discomfort and frequent evacuations ceased immediately after the operation or after the first irrigation, and within a few days the stools became almost normal, containing but little blood or mucus. It appeared to make but little difference what irrigating fluid was employed, provided that it was

used daily and in sufficient quantity to thoroughly cleanse the bowel. The operation had not been followed in any case by serious shock or great discomfort. Primary union occurred in all excepting two or three cases, where there were stitch abscesses. Only when the opening was small or showed a tendency to close was a catheter found necessary to enlarge the opening and allow free irrigation. The appendix was kept open for periods varying from three to twelve months, closing spontaneously in some cases, while in others it was necessary to cauterize the mucosa in order to close it. The only unpleasant sequela in the writer's series was a small ventral hernia. In one attempted appendicostomy the appendix was found short or completely occluded, necessitating its removal and the performance of cecostomy. In another case, the operation of appendicostomy was successful, but through-and-through irrigations were impossible because of a stricture of the transverse colon, which was detected at a second operation, when the appendix was removed and the abdomen closed. Dr. Gant then gave in detail the history of eight cases of appendicostomy and one of cecostomy, which demonstrated the value of these operations in ulcerative and inflammatory conditions of the colon, sigmoid, and rectum.

Dr. William H. Thomson said he would confine himself to a discussion of Dr. Kemp's paper, as the entire subject under discussion was almost limitless. He began by saying that we could treat disease successfully only by rational therapeutics, which were based primarily on an understanding of the nature of the disease. There was a radical and fundamental difference in nature between organic disease of the nervous system and functional disease of the nervous system—as much as there was between diabetes mellitus and smallpox. Nor should we treat functional nervous diseases and organic nervous diseases alike, because there was scarcely anything in common between them excepting the production of the nervous symptoms. For example, a case of hemicrania due to the presence of a syphilitic gumma was an instance of brain disease, although the patient might also suffer from vomiting and other symptoms. On the other hand, a case of hemicrania due to migraine was not an instance of brain disease. A case of general paralysis of the insane was again an instance of brain disease, while a case of melancholia had nothing to do with the brain. Organic brain diseases were always due to a demonstrable lesion or injury, or to a degeneration of some part of the nervous texture, while a functional nervous disease had nothing to do with the brain texture, but was invariably due to toxemia. It was of the utmost importance that we should recognize this distinction. With any derangement in the mechanism of an organ, there was a corresponding derangement in its function, or the mechanism of an organ may be perfect and the source of its function may be deranged. Thus all functions of the nervous system depended on the blood supply. In dealing with functional nervous diseases, the idea should first be gotten rid of that they were of less importance than those of an organic character. On the contrary, many of the more severe nervous diseases were purely functional. Among such might be mentioned tetanus, hydrophobia, and epilepsy; all functional nervous diseases, depending on the presence of certain toxins in the blood. Of course, the exciting causes of epilepsy were numerous, but the important factor was the toxin in the blood. An organic nervous disease, due to an actual change in the nervous texture, was permanent, while intermittency was a characteristic of all forms of functional disorders. There was absolutely nothing in the whole range of pathology that explained intermittency excepting a toxemic condition. The same was true of neurasthenia and hysteria, and the study of the toxemias that gave rise to these various functional nervous disorders was still in its infancy. In that connection the study of the processes of digestion, which had recently received so much attention, played a most important rôle. After referring to the interesting investigations of Pawlow in connection with the secretions of the gastrointestinal tract, Dr. Thomson said that unquestionably we had in those organs a more or less constant generation of toxins, in which the liver also took an important part. He was firmly convinced that it was along these lines that the solution of the problem of functional nervous diseases would ultimately be found. Since he had come to regard epilepsy in the light of a functional disorder, he had found that it was relatively a curable disease. Some of the most unpromising cases of many years' duration had yielded, not to the routine bromide treatment, but to treatment directed toward correcting an intestinal toxemia. The important point was to find the source of the poison. In hysteria, the attacks were almost invariably accompanied by a history of constipation. The function of the kidneys should also be investigated, as many of these patients habitually excreted a very low percentage of urea.

Dr. Achilles Rose said he wished to emphasize the point raised by Dr. Kemp in regard to the relation of certain mechanical conditions to various gastric and nervous disorders, and he called attention to the fact that the crosswise fibrous arrangement of the three flat muscles of the abdominal wall, the obliquus abdominis externus and internus and the transversus abdominis, was especially capable of effecting a narrowing of the cylindrical abdominal cavity. The abnormal effects of pressure and traction, as witnessed in atonia gastrica, caused pathological changes of the circulation and innervation. Ideas as to therapy would suggest themselves by balancing the various mechanical forces against each other, and by the intelligent exclusion of one factor or another. Mechanical expedients would in a great measure help in the achievement of good results. The object in utilizing mechanical force was to change the degree of involvement, to lighten overburdened points, and to place more work upon those which bore too little. That object we were able to accomplish by supporting bandages. Here there was a scientific foundation which in the chemistry of medicine was frequently conspicuous by its absence. Medicinal treatment was frequently but a blind experimentation with unknown quantities. This could best be seen by comparing the medicinal with the mechanical treatment of gastroptosia in some cases of neurotic affections, such as neurasthenia, hysteria, and mucous colic. It suggested itself to treat gastroptosia, which was present in most, if not all, of these cases, by means of plaster strapping. Such mechanical treatment must not necessarily be the exclusive therapy, but it may often be the most important. The speaker said he had also found the treatment by means of plaster strapping very satisfactory in cases of chronic diarrhea associated with atonia gastrica.

Dr. Edward Waitzfelder said he regarded the so-called functional diseases not as diseases, but as reflex manifestations from the cerebral or spinal centers, the irritation resulting from a change in the amount of blood supply. He believed they were hemic in their origin, and resulted from toxemia, which, acting on the smaller blood-vessels of the brain and spinal cord, induced a condition of either angiospasm or angioparesis, in all probability the former. He thought, speculatively, the condition was somewhat as follows: An error of digestion was followed by the production of certain (as yet unknown) bacteria, these germs and their toxins entered the blood, and the chemical irritation of these foreign substances on the centers in the brain and cord was followed by the nervous symptom-complex of the so-called functional nervous diseases, motor sensory, trophic, or psychic. The condition was parallel to that seen in the nervous symptoms accompanying chronic uremia, the toxemia of pregnancy, etc. Should this local angiospastic condition involve the vessels of the medulla and pons, a perversion of the functions of those organs would result, among which was a gastrointestinal angioparesis; this in turn would aid in the process of autoinfection, possibly by lessening the normal number of

phagocytes, enzymes, or other bactericidal agents, the nature of which would still have to be worked out. The speaker said he did not recognize hysteria, neurasthenia, chorea, exophthalmic goiter, epilepsy, or, in fact, any of the so-called functional nervous diseases, as an entity, but merely as nervous symptoms complex of a remote condition having a pathologicoanatomical or pathologicophysiological basis. He believed that the further development of pathological physiology would lead to a better understanding of the etiology of the so-called functional nervous diseases. He agreed with the previous speakers that the treatment of these cases should be carried on along the lines of causation, and not that of symptomatology; that the latter was merely blowing away the smoke, leaving the fire untouched. In the treatment of epilepsy, he believed that the elimination of toxins, together with the correction of errors of digestion by medicinal or mechanical means, would lessen the number of attacks, although he doubted that it would effect a cure after a number of years of the disease, when the "epileptic habit" had been established. In his opinion, after the function of a part had been impaired for a long time in consequence of an alteration in its nutrition, organic changes occurred of a fibrous, degenerative character, and an organic disease resulted, the lesions of which were permanent, and from which complete restoration of function was impossible. This was seen in epilepsy, exophthalmic goiter, paralysis agitans, and the various nervous diseases following arteriosclerosis.

Dr. William M. Beach of Pittsburg, Pa., said he firmly believed that colitis was a prolific cause of functional nervous disorders, and he expressed the opinion that the operaiton of appendicostomy, as applied by Dr. Gant, would be more generally practised in the future for the relief of chronic catarrhal conditions of the lower bowel after other methods of treatment had been exhausted.

The discussion was closed by Drs. Kemp and Gant.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 8, 1906.

Dr. Matthias Nicoll, Jr., in the Chair.

The Dosage of Diphtheria Antitoxin from an Experimental Standpoint.—Dr. William H. Park said that all knew that the diphtheria antitoxin was simply and absolutely used only against the toxin of diphtheria. Not only the poisonous substances produced by other bacteria, but even some of the intracellular poisons contained in the bodies of diphtheria bacilli were left unaffected by the diphtheria antitoxin. He said the question at issue was as to how much antitoxin injected into the tissue was required to neutralize the amount of diphtheria toxin produced in disease. He emphasized the point that when speaking of 1,000 units of antitoxin, one was speaking of a large amount of antitoxin, and that 10,000 units was a very large amount. The latter quantity was sufficient to neutralize five quarts of the strongest toxic bouillon obtainable. If all the antitoxin injected could meet the toxins as they were manufactured in the tissues it probably would not require a great amount of antitoxin to neutralize all that came from the tissues. The question arose as to how much toxin was present in each case. In diphtheria in man there was no way of judging this exactly, but in all probability, judging from animal experiments, there were not more than ten fatal doses for a man in the tissues of any case twenty-four hours prior to death; therefore, allowing for weight, each case would probably not have toxin to neutralize more than 100 units; probably not that much. This led one to consider the extent and rate of absorption of the antitoxin after the injection. If 10,000 units of antitoxin were inserted into the veins of a 1,500-gram rabbit and, one hour later, that rabbit's blood was tested, 30 or 40 units per c.c. would be found in the rabbit's blood. On the day following only 10 units per c.c., this drop from 30 to 10 units not necessarily showing any destruction, but possibly only the passing of the antitoxin into the general fluids of the body. If this same amount was given subcutaneously and the blood examined one hour later, instead of 30 or 40 units per c.c. being obtained, there would be obtained not more than 3 or 4 units. Therefore, it took a longer time for the antitoxin to get into the diseased tissues when administered subcutaneously than when given intravenously. If one wanted to get an immediate effect in a desperate case the antitoxin should be injected into the veins. Dr. Park, in considering the question as to whether one dose, or repeated doses should be given, said that while in moderate cases a single large dose was often sufficient, that several doses gave better results in bad cases than when a large amount was given at once. The administering of several doses would saturate the tissues several times. It must be kept in mind that antitoxin did not kill the bacilli, and in some cases a single dose, even when very large, did not seem sufficient. With regard to the length of time after the toxin had been injected and absorbed that antitoxin could be expected to do good, he said that he had tried to show this by giving animals ten fatal doses of toxin and, after varying periods of time, giving a certain quantity of antitoxin. In one animal, weighing 265 grams, to whom ten fatal doses had been given, and antitoxin one hour later, injecting 5 units, or five times the amount needed when given with the antitoxin, died on the seventh day. Another animal, weighing 330 grams, given the same fatal dose, with antitoxin given one hour later, .5 units injected, lived. Another animal, weighing 320 grams, that was given ten fatal doses, the antitoxin being given five hours later, 50 units being iniected, lived two and a half days, the same as one getting no antitoxin. Another animal, weighing 360 grams, and that was given four fatal doses, and the antitoxin being given one hour later, .04 being injected, died on the sixth day. Another animal, weighing 355 grams, that was given four fatal doses, the antitoxin being given on the fourth hour, 0.1 unit being injected, lived. From these and many more experiments it seemed certain that only a few hours could elapse after the blood had absorbed a fatal dose of toxin that antitoxin could have an effect. The greater the amount of toxin absorbed the shorter was the interval during which antitoxin was useful. He believed, with all the help possible from experiments, that the only way to get at the exact dosage of antitoxin was to watch carefully the cases receiving different doses. In hospitals the best way would be to have two series, one set treated according to those who believed in small doses, and the other according to the idea of those who believed in large doses of antitoxin, and then to alternate the cases. Dr. Park said that for three years he had studied experimentally the effects of large and small doses, alternating them, and he was fairly convinced on certain points. Those patients that received but 1,000 units at the first injection did worse than did those who received 2,000 units; the latter did not do quite as well as those getting 3,000 units. Those that received 1,000 units as an initial dose certainly did not get enough antitoxin, and the severe cases getting 2,000 units did not do nearly as well as one would confidently expect with larger doses. With still larger doses, however, the differences between those getting the different amounts was less and less manifest; thus, between those getting 6,000 and 12,000 units no definite differences were noted. During the last two years he personally had not had direct observation of the cases, but those who had charge of the diphtheria cases at the Willard Parker and Kingston Avenue Hospitals had informed him that the larger doses did better than the smaller ones. While not believing in the need of over 20,000 units in any case, he had not seen bad results from the administration of 30,000 to 50,000 units.

The Dosage of Diphtheria Antitoxin as Administered in the Hospitals of the Department of Health. — Dr. Wm. E. Studdiford presented this communication, which was read by Dr. Park. The majority of the cases entered the hospitals at the beginning of or the end of the third day, and a large percentage of them were laryngeal cases. About one-third of the deaths occurred within the first twenty-four hours. At the Riverside Hospital there were 563 cases, with 43 deaths, a mortality of 7.5 per cent. The tube cases numbered 269, with 123 deaths, a mortality of 45 per cent. The general mortality among 832 cases showed 166 deaths, a mortality of over 19 per cent. The maximum dose of antitoxin administered was 40,000 units, the minimum, 2,000 units, an average dose being 15,000 units. In the ordinary cases the maximum dose of antitoxin administered was 70,000, the minimum dose, 2,000, with an average of 10,000 units. There was among these a mortality of 6.4 per cent. Excluding the moribund cases, the mortality was 5.2 per cent. At the Kingston Avenue Hospital the total amount of antitoxin administered was 3,340,025 units. The total number of cases was 211. The average dose of antitoxin given was 11,090. The maximum dose was 45,000 units, the minimum dose, 2,000 units. The total number of tube cases was 65, with 34 deaths, a mortality of 52.3 per cent. Of these 65 cases 27 recovered, 34 died, and 4 remained. The total number of straight cases was 146, with 16 deaths, a mortality of 10.9 per cent.

New Preparation of Diphtheria Antitoxin.—Dr. Park said that a new preparation of antitoxin was gradually being given on the fourth hour, 0.1 unit being injected, next month (March), nothing but this would be supplied. It had seemed to him for years that they should get rid of much of the deleterious matter in the antitoxin, which gave rise to rashes, joint symptoms, etc. In 1900 Mr. Atkinson, the chemist in the Research Laboratory of the New York Board of Health, fractionated the serum and got rid of all but the globulin substances. This was tried in children, but it did not seem to give rise to less rashes than did the whole serum. About a year and a half ago Mr. Gibson improved on Mr. Atkinson's work by eliminating about one-third of the globulins. The question then was, Would this serum with albumins, non-proteid constituents, and about one-third of the globulins removed, give better results? At first many rashes developed, and then Mr. Gibson tried one modification after another, and, by and by he learned that it was rather the condition under which the globulins existed rather than their presence which was most important. He thus finally obtained an antitoxin solution which at present gave less rashes. In 200 cases only about 8 per cent. showed rashes and these were moderate urticarias. In all probability further fractionating was possible. The Health Department would furnish, after next month, only two strengths, one of 500 units per c.c., the other of 800 units. The serum would be supplied in 1,000, 2,000, 3,000, and 5,000 unit vials. In a few stations vials of 10,000 units would also be supplied. So far as the effect upon children went, there might be no harm in giving 15,000 or 20,000 units; but when only 5,000 or 10,000 were needed, that amount only should be given, because it was a serious matter to add so greatly to the cost of treatment, whether that was borne by the individual or the State. Dr. Park requested that, if rashes developed during the use of this new antitoxin serum, he might be notified by the physician in charge of the case.

Dr. John S. Billings, Jr., said that the inspectors of the Department of Health in Manhattan administered diphtheria antitoxin in 2,849 cases last year; of these 1,123 were proven not to be diphtheria, or admitted to the department hospitals and counted in their figures. Of the 1,726 diphtheria cases injected by the inspectors and remaining at their homes, 95 died, a mortality of 5.5 per cent.; there were 240 laryngeal cases and 41 died, a mortality of 15 per cent.; the number of cases intubated by the inspectors was 48, and 11 died, a mortality of 23 per cent. In 1904 the mortality among the operative cases was 44 per cent., just double what it was in 1905, and he could give no reason for this. In the borough of Manhattan in 1905 there were reported 7,553 cases of diphtheria, with 660 deaths, a mortality of over 11. The inspectors injected 1,726 of these and obtained a mortality of but 5.5 per cent. There were 642 cases treated in the hospitals, with 120 deaths, a mortality of 18.5 per cent. There were 684 cases reported by physicians who injected antitoxin furnished free by the Department of Health, with 68 deaths, a mortality of about 10 per cent. If now the three classes of cases be added together and deducted from the total, it would be shown that there remained about 4,500 cases and 377 deaths, a percentage of about 8 per cent., a very good showing, indeed. In Brooklyn the mortality was about 12 or 14 per cent., while in Queens it was 13 per cent., and in the Bronx, 20 per cent. The inspectors used for the first dose, as a rule, from 2,000 units up, seldom using as much as 7,000. In the average case they used about 5,000 units, although in very severe cases they might use as much as 7,000 or 8,000, and occasionally 10,000.

The Dosage of Diphtheria Antitoxin in Private Practice.— Dr. Charles Gilmore Kerley said that with the increased knowledge gained from the successful employment of antitoxin in many cases we were now in a position to lay down more definite rules for its administration. It had been learned at what period of the disease antitoxin could be given to the best advantage, the necessity for a variation in the dosage in the different forms of diphtheria, and the clinical signs which called for a repetition of its use and its dosage at such repetitions. The ultimate amount of antitoxin which a given case might require could only be determined by noting the effects as produced on the disease. Early in the use of diphtheria antitoxin 1,000 units was given as the initial dose; now many physicians rarely gave less than 5,000 units, even though the case was seen on the first or second day. He stated that in regard to dosage he made no age distinction. In diphtheria we could not temporize or trust to chance, no matter how mild the case might appear at the onset. On the first or second day 5,000 units was given. In the majority of his cases, when this large initial dose had been given, a repetition was not necessary in the non-laryngeal cases. Even if a child recovered under repeated small injections, the attack was prolonged, increasing the chances of various complications. If improvement was not apparent in eight or twelve hours, as indicated by a broken granular appearance of portions of the membrane, with lowered temperature and improved general condition, the dose was repeated not later than twelve hours after the first injection. If an extension of the membrane had taken place, double the amount, 10,000 units, should be given. If the case was seen on the third day with marked toxic symptoms, 10,000 units should be the initial dose, and should be repeated at ten- or twelve-hour intervals until no longer required. In laryngeal cases 5,000 units should be the initial dose, repeated in eight hours if relief did not follow. He cited a case in which 11,000 units were given in nine hours, and another in which 9,000 units were given in twenty-four hours, both of which recovered. In his observation laryngeal intubation cases required from 10,000 to 15,000 units, even when used early. Antitoxin should be used even in apparently moribund cases. In mild nasal cases without fever 3,000 units had been sufficient to clear up every case. For immunization not less than 1,000 units should be given. In several cases in which he had known diphtheria to develop within a few days after an immunizing dose the patients required smaller subsequent dosage than was necessary in those by whom they were infected.

Dr. B. Franklin Royer of Philadelphia, in discussing Dr. Kerley's paper said we should strive to harmonize our views as nearly as possible in regard to the dose of antitoxin required for diphtheria in the various sites. We

should try to learn the number of hours that might elapse after absorption of toxin before chemical action with body cells took place. From experiments it was evident that we could do nothing with toxin absorbed twenty-four hours ago. He thought that manufacturers of antitoxin and boards of health were responsible for the small doses given in private practice. It would seem advisable to have antitoxin dispensed in larger-sized doses than it was at present. If larger doses were given fewer injections would be necessary, and the public dread of administration would be decreased. In his experience at the Municipal Hospital in Philadelphia, during twenty-nine months, more than 2,400 diphtheria patients were admitted. While treating these they had striven to determine the dose suitable to the various conditions. They had concluded that the best guides to determine the dose were, first, the amount of pseudomembrane present; second, the location of the pseudomembrane; and third, the duration of the disease. Age was not considered in determining the number of units to be injected. A single tonsil covered with pseudomembrane required a small dose; both tonsils covered, with overlapping of pillars and appearance of membrane on the uvula meant that a still larger dose was to be injected; while with these parts involved and nasal, pharyngeal, or laryngeal involvement a very large dose was indicated. The location of the exudate was important. If the disease was of nasal or nasopharyngeal type it was more highly toxic than if in other locations. Mechanical removal of toxin from the tonsils by washing a portion of it into the esophagus, diverting a portion to the stomach, might secure a lessening of toxicity by action of digestive fluids. With exudate in the larynx and trachea we could judge of the amount present only by the stenosis and prostration. Here, too, a large dose was indicated. The initial doses were as follows: A single tonsil covered with pseudomembrane, 2,500 units; both tonsils covered, 5,000 units; both tonsils and pillars or uvula, 7,500 units; nares and larynx, 7,500 or 10,000 units; nares and larynx, or tonsil and larynx, 7,500 to 10,000 units. We might repeat the dose in twelve hours in greatly prostrated cases or anginose cases. On each successive morning until the pseudomembrane had disappeared, in good part, an injection as large as the initial dose, or as much smaller as the remaining exudate would seem to require, was given. He favored twelve- and twenty-four-hour intervals with large doses, as it lessened the occasion of giving pain and the danger of infection. The dose might not yet be large enough, but the mortality among patients reaching them the first day had been nil, while among those coming the second day the mortality had remained below 5 per cent., this including many laryngeal cases. The death rate among patients admitted the third day had been about 12 per cent., and those coming later showed higher death rates.

Dr. L. Emmett Holt believed that the amount of membrane in a given case was a better guide than the age in determining the initial dose. Antitoxin was not given early enough, nor did one use, as a rule, large enough amounts. A single large dose at the start, he said, would accomplish as much as two or three times that amount when given later. It was impossible to tell at the beginning of the disease whether the case would be a bad one or not, or whether much toxin would be produced; therefore it would be decidedly better not to give too little. The secret of success in the treatment of diphtheria lay in giving a single large dose as early in the disease as possible. The Boston statistics, in his opinion, did not show any better results than elsewhere where such enormous doses of antitoxin were not given. He hoped that the Health Department would provide a larger number of units in their packages.

Dr. William P. Northrup emphasized the importance of giving the antitoxin as early as possible with an initial dose of 5,000, preferable 6,000 units. The prophylactic dose was from 500 to 1,000 units. To show that large doses would not have a very deleterious effect, he referred to one case of cerebrospinal meningitis that was given 125,000 antitoxin units and it did not kill.

Dr. Henry W. Berg said that the problem in all cases was to introduce sufficient antitoxin to antagonize not only the free toxins in the blood, but the toxins which had become united with the animal cells, particularly those of the heart muscle. The combined and semi-combined toxins were important elements to be considered in giving the antitoxin. As guides to the amount of antitoxin to be given, he made use of the pulse and temperature, and not the extent of the membrane, which was Dr. Royer's guide. Every case of diphtheria had a rapid pulse, due to a myocarditis, and if he found the pulse would not go down within twenty-four hours after the injection of the antitoxin the dose was repeated. When temperature was present, after a single injection of antitoxin it would drop, as a rule, by crisis; there would be either a crisis or a pseudocrisis. If this did not occur, the dose of antitoxin was repeated. Behring of Germany gave less antitoxin than was given in this country. Dr. Berg had never had occasion to inject more than 6,000 or 7,000 units, even in the very severe cases. He did not believe in extravagant doses.

Dr. Henry Koplik said that the uncomplicated cases of diphtheria should be separated from those that were complicated or the bottom of the question would never be reached. In the kind of cases described by Dr. Royer, the bull-neck cases, in which the gland involvement showed a mixed infection, and, in some cases, a pneumococcic infection, he had seen them liberally dosed with antitoxin, the mucous membrane clearing away, and yet the patient died apparently from the mixed infection, probably a streptococcic infection. The uncomplicated cases of diphtheria were easily managed.

Dr. H. Norton Mason said that at the New York Infant Asylum during the past four months immunizing doses of antitoxin had been administered to four hundred patients, 1,000 units for adults and 500 for children. They all failed to contract diphtheria when exposed to it. No untoward effects from the antitoxin resulted save a few cases of urticaria and two or three cases of a slight rash, which lasted about twenty-four hours.

Dr. Louis C. Ager of Brooklyn said that the antitoxin of diphtheria was not used so universally in Brooklyn, because of the prejudice engendered against it caused by an unfortunate result occurring in the practice of one of the most prominent physicians there. Three deaths from heart failure following its use in small doses were reported; he believed that if larger doses had been given these deaths would not have occurred.

Dr. L. E. La Fetra emphasized the importance of seeing the cases of diphtheria often and noting if improvement took place during the course of treatment; if improvement had not taken place after the initial dose of antitoxin, then that initial dose had not been large enough. The toxins were manufactured in the body and united chemically with the cells, especially of the nervous system and myocardium, and it was very important to neutralize them as early as possible. For an initial dose he advocated giving from 3,000 to 5,000 units; if at the end of twelve or twenty-four hours the membrane did not begin to curl up, the dose of antitoxin proper for that time should be given.

Dr. L. Emmett Holt considered 3,000 units to be a fair early dose of antitoxin in most cases of diphtheria.

Dr. Charles G. Kerley believed that it was far better to use an initial dose of antitoxin of 6,000 units; even if that was more than the child required it would do no harm. Too much stress was laid upon the amount of pseudomembrane present; the important point to consider was, had the child diphtheria?

Dr. William H. Park, in answer to Dr. Royer's question, said that when antitoxin was injected under the skin

it was absorbed about one-half as rapidly as when injected into the muscles; but when injected into the veins, it was at the end of an hour six times as abundant as when injected under the skin. He thought that all were in accord that the first dose should be large, and also that if one gave a large dose of antitoxin, and within twelve hours no improvement was noted, a second or even a third dose should be administered. He doubted whether one could give in every case such a large initial dose that a second would never be required. With regard to immunizing doses, Dr. Park did not believe that more than 1,000 units were necessary. The limit of its usefulness as an immunizing agent might be reached in ten days, and then another dose might be required.

Dr. Berg asked Dr. Park if he understood him as recommending the injection of antitoxin directly into the veins.

Dr. Park replied that in those cases in which a fatal termination was feared he would advise an intravenous injection, but not in the ordinary cases. In the reports of cases so treated no mention had been made of any bad effects.

BRITISH MEDICAL ASSOCIATION.

Seventy-fourth Annual Meeting, Held in Toronto, August 21, 22, 23, 24, and 25, 1906.

(Special Report to the Medical Record.)

(*Concluded from page* 434.)

Intestinal Obstruction in Association With the Vermiform Appendix.—Mr. George Gray Turner of Newcastle-on-Tyne read this paper, and, for the sake of convenience, considered his subject under the following headings: (1) Obstructions due to appendicitis, or its results; (*a*) during acute attack, (*b*) during convalescence or after operation for acute appendicitis, (*c*) in recurrent cases, or after interval operations, (*d*) at some period remote from the acute attacks. (2) Obstructions produced by the appendix, but without appendicitis. To show the frequency of intestinal obstruction he said he had collected forty-seven cases in six years, and he showed that its frequency was one obstruction to fifty-three cases of appendicitis. There were in his series of cases but three cases of obstruction due to appendicitis occurring during the acute attack, and he related the histories of these patients. There were twenty-three cases of obstruction occurring during convalescence, or after the operation for appendicitis. The average time of the onset after operation was twelve days, and the obstruction was most commonly due to shrinkage of an abscess. Obstruction caused by bands was not so common. There were but two cases among the recurrent, or after interval cases, and the pathology in these did not differ from that noted in the remote cases. This was made a distinct group, in order to emphasize the danger. There were nineteen instances of obstruction occurring at some period remote from the acute attacks; the average length of time of the onset was three years and six months. The longest interval was seventeen years, and the shortest was four months. Acute obstructions were most common. The most difficult cases were those which had recovered from general septic peritonitis. He insisted upon early operation in all acute cases.

Dr. N. A. Powell of Toronto dealt with some personal experiences and with some points in treatment. He said that obstruction at the time of an attack, or following an attack, must be comparatively rare. His personal experience was limited to but two cases out of 350 submitted to operation. In one case, that of a young man, he had to operate at night in a badly lighted room; in this case the peritoneal edges were not approximated properly and angulation and strangulation followed. The second case was a wonderful one. Eight hours after the beginning of his third attack of appendicitis, Dr. Powell was consulted. Operation was performed twenty-six hours after the initial symptoms. On the fifth day the patient began to have pain, with distention of the upper half of the abdomen, and vomiting frequently. Upon opening the abdomen a distended coil of black intestines presented. The appendix wound was in perfect condition. On the left side there were old and dense adhesions, forming an annular band. Conditions were very bad, and he was compelled to evacuate the bowel by means of a tube, which he presented. This was very difficult because of the great danger of soiling the peritoneum. He then excised over two feet of intestines, and brought the divided ends together, using Murphy's button, which was passed five days after operation. This patient, in spite of his frightful condition at time of operation, made a good recovery. He emphasized the great importance of preventing the chilling and drying of the exposed bowel by running hot saline solution over it.

Dr. J. B. Murphy of Chicago appreciated the insistence upon early operation. There was no time for procrastination when there were evidences of intestinal obstruction.

Congenital Dislocation of the Hip.—Dr. Jenkins of King's College, London, explained this condition on developmental grounds, as arising from the prechondral stage. He made blackboard drawings to make his explanation clear.

The Treatment of Acute Septic Peritonitis.—Mr. Charles John Bond of Leicester read this paper. He first considered the physiology of the peritoneum with special reference to the great importace of the diaphragmatic portion, and the peculiar sensitiveness of that covering the small intestines. Under pathology he told of the way in which the peritoneum reacted to infection and the protection of the endothelial layer by the formation of a fibrinous deposit. Chemical peritonitis was not seen clinically. The peritonitis accompanying the intraperitoneal extravasation of blood was generally due to the *Staphylococcus albus*. Gonococcal peritonitis was not of a very high degree of virulence. In ruptured gastric and duodenal ulcer, the infection was not highly virulent, but the necessity for immediate operation was most urgent. The infection could be frequently arrested by irrigation, with or without drainage. Septic peritonitis due to infection from the alimentary canal below the duodenum was then considered. The frequent and early migration into the peritoneum of the *Staphylococcus albus* in many cases of septic peritonitis acted beneficially by stimulating phagocytosis, and had an important bearing on the treatment and the question of irrigation. Streptococcal peritonitis was highly virulent and generally fatal, in spite of treatment. He referred to the frequency of pneumococcal peritonitis in female children, and the primary and secondary varieties, and the importance of the observation of the naked-eye characters of the exudate and the appearance of the inflamed membrane, especially in this variety of peritonitis. After speaking of the treatment by drugs, morphine, purgatives, serum, and expressing a want for a polyvalent antibacillus coli serum, he took up the surgical treatment. He emphasized the importance of respecting the diaphragmatic area, and the risk of removing phagocytes by indiscriminate irrigation. The prime object was to attack the primary focus of invasion and arrest further infection. The next point was to treat the infected general peritoneal cavity. In cases of moderate severity the safest course was the efficient treatment of the primary focus by dry sponging or local irrigation and drainage, combined with the least amount of interference with the general cavity, unless collections of fluid exudate in the pelvis or loins required drainage. Highly virulent streptococcal infections might require free irrigation, with even partial evisceration. Cases of slight virulence were best treated by free irrigation, either with or without subsequent drainage. In giving his general conclusions, he said that irrigation was beneficial where the peritoneum contained foreign material capable of removal by

flushing, such as blood, gastric or duodenal contents, fecal matter, pus, infected urine, or bile. It was harmful in cases of fibrinous, sticky exudate, and when used to wash away a turbid exudate containing active phagocytes, or when instrumental in spreading infection. Free drainage or tamponage was essential in the treatment of local abscesses, necrosis of bowel, or where the treatment of the primary focus of invasion must be necessarily incomplete. It was generally harmful when used in the upper peritoneal area, unless this was primarily infected. It was generally of little use in the small intestine area. It was most frequently useful in the lateral areas and in the pelvic basin. The efficiency of peritoneal drainage depended on the integrity of the endothelium in the area drained.

Dr. William Howitt of Guelph said he wished to emphasize the deleterious effects of morphine; its administration should be condemned in every case in which there was the slightest suspicion of the existence of peritonitis. In postoperative treatment only evil effects followed the use of opiates. Purgatives should be condemned as well. In the absence of pronounced bowel distention the important points to be borne in mind in the surgical treatment were early operation, gentle but complete removal or adjustment of the cause of the septic peritonitis, and irrigation when not contraindicated and provided there was a free escape for the fluid. Judicious drainage and posture were of the utmost importance. Hypodermics of strychnine and saline solution by rectum and subcutaneously played an important rôle in the treatment. He preferred the posterior method of draining, using a perforated flexible rubber tube. In females it was introduced through the vaginal wall; in males, through a stab wound in the lumbar region. Fowler's posture should be adopted before operation. Out of thirty-four desperate cases he had been able to save all but five.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Transactions of the American Ophthalmological Society. Vol. X., Part III. 8vo, 661 pages, illustrated, paper. Published by the Society, at Hartford.

Medizinal-Berichte ueber die Deutschen Schutzgebiete, für das Jahr, 1903-04. 8vo, 305 pages, illustrated, muslin. Ernst Siegfried Mittler und Sohn, Berlin. Price, 7.50 M.

Infection, Immunity, and Serum Therapy. By H. T. Ricketts, M.D. 12mo, 600 pages, muslin. The American Medical Association Press, Chicago, Ill.

Progressive Medicine. Edited by Hobart Amory Hare, M.D., assisted by H. R. M. Landis, M.D. Vol. I. March, 1906. 8vo, 304 pages, paper. Lea Brothers & Co., Philadelphia. Price, $6.00 per annum.

A Nurse's Hand-Book of Medicine. By J. Norman Henry, M.D. 8vo, 268 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia.

Second Annual Report of the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis. 8vo, 452 pages, illustrated, paper. The Henry Phipps Institute, Philadelphia.

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Reciprocity.—Dr. E. B. Harvey, Secretary of the Massachusetts State Board of Examiners, objects to so-called interstate reciprocity. In the *Journal of the American Medical Association* he emphasizes the various methods at present prevailing in different States; he also contends that the practice of admitting and recognizing the credentials of physicians from other States, and allowing them to practice without further examination, destroys the protection against incapacity. He further maintains that reciprocity confers exclusive and unfair privileges on outsiders, and that it tends to lower the standard of medical education. By quotations from statistics he shows the laxity of some States as compared with others; and he claims that the migratory incompetent is the man who benefits by reciprocity.

Illinois now reciprocates—in the case of licenses issued after examination—with the following States: Indiana (after January 1, 1905, only), Iowa, Kansas, Maine, Maryland, Michigan, Minnesota, Nebraska, New Jersey, North Dakota (after July 1, 1905, only), Ohio, South Carolina, Vermont, Wisconsin, and Wyoming. The Illinois State Board of Health does not reciprocate in the case of licenses issued on the presentation of diplomas, without examination. The Illinois State Board of Health subjects all applicants for a State certificate to practice medicine in Illinois, to an examination, in accordance with the provisions of the medical laws of the State of Illinois, and allows, in the examination, a credit of five per cent. on the required average of seventy-five per cent. for each five years of reputable practice since graduation. At the recent examination (in July) sixty-four physicians were successful out of a total of seventy-six.

Texas.—At the June examination there were one hundred and forty-four applicants; of this number one hundred and two were successful.

District of Columbia.—At the July examination twenty-four candidates were successful and twelve failed to pass.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 15, 1906:

	Cases	Deaths
Tuberculosis Pulmonalis	351	150
Diphtheria	184	19
Measles	53	2
Scarlet Fever	74	4
Smallpox	2	—
Varicella	6	—
Typhoid Fever	134	18
Whooping Cough	38	7
Cerebrospinal Meningitis	14	5
Malarial Fever	.....	.....
Totals	856	205

Preliminary Report on Bacillus Muco-aërogenes Capsulatus.—Wm. Litterer describes an organism belonging to the group of the *Bacillus mucosus capsulatus*. He states that there are certain peculiar cultural characteristics of this undescribed member that render it so very different from all other species that a separate and distinct class is apparent. Last year this bacillus was isolated from a virulent case of gangrenous appendicitis, and about six months later the identical germ was again demonstrated in a case of gangrene of the intestines. Inoculations of this organism are highly virulent for the ordinary laboratory animals. When the organism was weakened by artificial cultivation and then inoculated subcutaneously there invariably developed gangrene at the site of inoculation. The formation of gangrene is greatly increased by the presence of other bacteria. This organism will ferment all sugars except saccharose, and is able to form a small quantity of gas from proteids, as shown by its being produced in a dextrose-free gelatin stab, as well as in the fermentation tubes of sugar-free bouillon. When planted on agar slants, the organism has a marked tendency to grow anaërobically, as evidenced by its burrowing into the solid culture medium which tends to break up. Gas bubbles develop in the substance of the solid media, even though the bacteria are on the surface. No special staining method is necessary to demonstrate the capsule.—*Nashville Journal of Medicine and Surgery*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending September 15, 1906:

PERCUSSION OF THE SKULL AS A MEANS OF PLACING THE INDICATION FOR THE PERFORMANCE OF LUMBAR PUNCTURE;

WITH SPECIAL REFERENCE TO ITS APPLICATION IN CEREBROSPINAL MENINGITIS OF THE EPIDEMIC TYPE.

By HENRY KOPLIK, M.D.,

NEW YORK.

LUMBAR puncture as first practised by Quincke may be applied both as a diagnostic and therapeutic agent. As a diagnostic means of precision, it has become of great utility, not only in making a diagnosis of the presence or absence of meningitis, but of the various types of meningitis, especially of the seropurulent or tuberculous variety. As a method of diagnosis we apply lumbar puncture in those cases, in which clinically there are the symptoms of meningitis, but in which the symptoms are to a certain extent indefinite, and in which it is necessary to establish firmly the diagnosis of meningitis in a broad sense, or, being certain of the presence of meningitis, to fix its specific nature, whether tuberculous, meningococcic, or otherwise.

The nature of the fluid withdrawn may be negative to such an extent as to still leave doubt as to the exact diagnosis; such may be the case in brain tumor, or in serous meningitis, complicating otitic disease, or in cases of old cysts of the brain with reaccumulation of contents. In such cases there may have been a preceding abscess of the brain, which apparently remained after the causal mastoiditis had been healed. After a few years a cyst formation in the cerebral region may burst into the subarachnoid space, and give rise to symptoms simulating meningitis. The subarachnoid fluid, in such cases, may even become contaminated by streptococci, and mislead into a diagnosis of streptococcic meningitis. In spite of these drawbacks, however, lumbar puncture is our most valuable means of precision in cases which show clinical symptoms on the border line between various forms of serous, purulent, and tuberculous meningitis.

It is not the purpose of this paper to discuss this phase of lumbar puncture, but rather to fix definitely the therapeutic application of the procedure. As a therapeutic measure, lumbar puncture is applied in the various forms of hydrocephalus, acute and chronic, whether congenital or due to a preceding meningitis. It is applied in the various forms of meningitis, either to simply remove fluid as a mode of drainage, or to remove excessive fluid, which is causing pressure, and thus to relieve symptoms, if not to save life. Of questionable use as a therapeutic measure is the application of lumbar puncture in cases of tumor of the brain to relieve headache, questionable, because the removal of fluid in such cases is not devoid of danger to the life of the patient, even when the greatest precautions are employed, such as the use of a manometer for the registration of intracranial pressure. Even when these precautions are employed, the withdrawal of fluid may be followed by the sudden death of the patient. A questionable use of lumbar puncture as a therapeutic measure, is in cases of encephalitis, or so-called coma dyspepticum, or in pneumonia with cerebral symptoms; in the last disease mentioned lumbar puncture has been proposed as a means of relieving cerebral symptoms, such as delirium and headache, which we will show in pneumonia are not always due to an accompanying serous meningitis, but rather to toxemia, and thus no pressure can be relieved in these cases by lumbar puncture.

As a therapeutic measure, lumbar puncture was first introduced by Leonard Corning as a means of injecting drugs into the spinal space, and thus causing anesthesia. We will not discuss this therapeutic use of lumbar puncture.

As a therapeutic measure, we will consider more specifically the application of lumbar puncture in cerebrospinal meningitis, especially of the acute epidemic type. There is no monograph extant which will give the student any idea as to when the proper moment arises in this disease, either to apply lumbar puncture for the first time, or when to repeat it, after having once carried it out. All monographs speak of the relief of symptoms, such as excitement, sopor, delirium, headache, hyperesthesia, and convulsions in such a manner as to confuse a physician hopelessly, for it may be said here that there are certain cases of meningitis, in which these symptoms are present, but in which lumbar puncture need not be performed. Again, we are repeatedly told that lumbar puncture is performed to relieve pressure on the structures at the base of the brain and subarachnoid space, but there is no work at our disposal, which will tell the physician how to diagnose intracranial pressure, as actually present, before proceeding to puncture. There may be sopor, delirium, excitement, hyperesthesia, headache present in a case of meningitis as a result of toxemia without the presence of intracranial pressure.

Given a case of meningitis, the first result of intracranial pressure is an acute, subacute, or chronic distension of the ventricles of the brain with fluid, and it is the early detection of this fluid which gives us the absolute indication to relieve distension by lumbar puncture. The mode of detecting acute hydrocephalus, whether caused by acute distension of the ventricles on the first day of a cerebrospinal meningitis, or during the slow, insidious onset of a tuberculous meningitis, is by percussion of the skull. McEwen, in his work on the pyogenic diseases of the brain and spinal cord, describes very accurately the elicitation of a differential cranial percussion note, in which he shows that in various conditions, such as cerebral tumors, the lateral ventricles are distended with serous fluid. In such cases the per-

cussion note elicited at a given spot on the cranium, such as the pterion, varies according to the position of the head. While the person sits with the head upright, the most resonant note is brought out by percussion of the skull by means of the finger as in chest percussion towards the basal level of the frontal bone, and the squamous portion of the parietal. The percussion on the lower bone, as the head is inclined to one side, gives a tympanitic note. As McEwen says, the exact musical quality of the note is difficult to describe, but when heard gives an idea of hollowness. McEwen found this note in over forty children and young adolescents, who had distended ventricles due to various causes.

I have pointed out elsewhere that in children below two years of age, if there has been rachitis, even though the sutures and fontanelles are closed, we may obtain a tympanitic note, due to some excess of fluid in the ventricle of the brain, the children presenting no other abnormality.

In no work do I find any data as to the application of percussion of the skull in cases of cerebrospinal meningitis. I consider percussion of the skull the only definite means we have to-day of determining whether there is an increase of fluid in the ventricles or the subarachnoid space causing pressure effects, and therefore demanding immediate relief. I have recently shown in a paper read before the Association of American Physicians that there are cases of cerebrospinal meningitis with marked cerebral symptoms, in which puncture is scarcely indicated, because, though there are delirium, headache, hyperesthesia, and sopor, we cannot demonstrate that there is any increase of fluid in the subarachnoid space and ventricles of the brain; therefore, lumbar puncture would not relieve pressure or symptoms.

The early idea of utilizing lumbar puncture as a method of *drainage*, by which a certain amount of purulent or suppurative fluid is removed from the inflamed district is, I think, a rather unscientific mode of treatment, of at least one form of meningitis, the meningococus type. For this disease is self limited, and the physician should be ready to tide over critical periods of the disease, such as we see when intracranial pressure becomes extreme. We can best demonstrate our method of carrying out lumbar puncture by illustrating with an acute case.

Child, five years old, was taken ill with a slight sore throat and a high febrile movement with vomiting. Fever continued for twenty-four hours; there was some headache, but not to a great degree. The child was siting up in bed and playing with its toys. Suddenly, without warning, it became pale, the pulse rapid and feeble, the temperature rose to 105°, the surface of the body was pale. The child lay back in a collapsed condition, with shallow breathing, becoming quickly unconscious, and in this condition was seen by me with the attending physician. I found a child of delicate nutrition, unconscious, with sighing, labored respiration, rapid, feeble pulse, cold surface, and with very minute petechiæ on the inner side of its arms, scarcely noticeable, pupils dilated. Percussion of the skull on either side gave a hollow tympanitic note, evidence of an acute distension of the ventricles by fluid. The pulse in this case was 150, the respiration sighing and irregular. The diagnosis of distension of the ventricles by fluid thirty hours after the onset of cerebrospinal meningitis was made. Lumbar puncture was urged, and proved in the first place that we had really a case of cerebrospinal fever of the meningococcus type, and secondly that the fluid in the subarachnoid space was under great pressure, fully 50 c.c. being withdrawn before it seemed that the pressure was normal. After puncture the conditions of collapse, headache, depression, and cerebral prostration improved; after days the mental condition cleared up, and the patient made an uncomplicated and speedy recovery.

In another case to which I was called recently a child of six years had been ill for thirty-six hours. He began with fever and headache, and on the morning of the subsequent day he vomited and seemed a little more stupid than he had been. He developed a few petechiæ on his body. The sopor deepened into stupor, and toward evening of this day the patient was unconscious, had all the classical signs of a cerebrospinal meningitis, his body was covered with petechiæ, and he had also an exquisite tympanitic note by percussion over the ventricles of the brain, and on this indication lumbar puncture was immediately advised. I understand the child did well.

On the other hand, percussion of the skull by the method which I have described, is a useful mode of differentiating those cases of so-called meningism or the symptom complex of cerebral symptoms from the severer types of meningitis. I have seen cases of pneumonia with cerebral symptoms, in which it was proposed to puncture in order to relieve symptoms, or to diagnose the presence or absence of meningitis. The following case is illustrative. A short synopsis alone is necessary.

Female, four years of age. Past history: Had measles—no sore throats. Had pneumonia at one year. Since then has had slight dyspnea, cough and cardiac palpitation, and precordial pain on slight exertion. Bowels regular, urination normal. Present illness: Began suddenly three days ago with severe headache, anorexia, vomiting, and high fever; no chill or chilly sensations, convulsions, or cough. Two days ago symptoms continued about the same. Child always bright mentally. Delirium. One day ago neck was stiff for a few hours. Headache somewhat milder, vomiting stopped, but anorexia continued. No involuntaries. Chief complaints: Headache, vomiting, fever, anorexia, delirium. On admission to the hospital the child was of good physique, was delirious and irritable. There was some rigidity of the neck and a distinct Kernig. The child was hyperesthetic, and had, in short, all the symptoms of a beginning meningitis. The chest examination on the left side behind showed dullness and rude respiratory murmur from the angle of the scapula down, which two days subsequently developed into a distinct pneumonic consolidation, thus clearing the case. In this child percussion of the skull from the outset failed to give any signs of fluid causing pressure, or, as I call it, McEwen sign, and therefore this case was not punctured, though I feel that it so resembled a meningitis that the enthusiast might have been justly led to puncture on the ground of relieving the delirium and restlessness. In two days, however, our supposition that meningitis was only simulated was supported by the development of the pneumonia and the clearing of the mental state. I have histories of other cases of pneumonia with cerebral symptoms in which the careful percussion of the skull failed to reveal any increase of fluid in the ventricles or the tympanitic sound described with hydrocephalus. As a corrollary this would seem to disprove the supposition that in cases of meningism there is always a serous meningitis. If this were so, we would obtain a tympanitic note on percussion of the skull in these cases. In the absence of signs of fluid in the ventricles, we conclude that the meningism in such cases is due more to toxic than pressure effects.

These cases are simply brought forward to show on what grounds we can definitely conclude that not only is there an increase of pressure, but that, if we do puncture, we may be rewarded by relieving that pressure. I may say that this method, to my mind, presents the only indication for the performance of lumbar puncture.

Another case, which shows distinctly that at the beginning of the disease puncture is not necessary, but may become so in the course of the affection, is the following: A boy of nine years was taken ill with the typical symptoms of cerebrospinal fever of the moderately severe type. He had been perfectly well previously; had partaken of some indigestible food, complained of headache, and vomited once. He then developed rigidity and other symptoms of cerebrospinal fever, and ran a temperature at the outset which ranged from 102° to the subnormal, or from 105° to the subnormal daily. This boy, being highly intelligent, was conscious during the whole course of the disease up to the period to which I am leading. I percussed his skull every time I saw him in consultation almost daily, but failed to find any evidence of distension of the ventricles with fluid. In other words, no acute hydrocephalus. I advised against puncture. On the twentieth day of his disease, the headache which had been quite severe and accompanied by abdominal pains became more insufferable. He vomited and had chilly sensations; he passed gradually into a state of sopor within a few hours. At this time percussion of the skull revealed a tympanitic note over the left ventricle of the brain. Puncture was advised, and was rewarded with a slightly turbid fluid under considerable pressure, falling to the normal when 40 c.m. had been removed. Fortunately for this little patient, after the relief of the ventricles by this one puncture he became brighter, although still complaining of headache and pain in his ears, became more rational, his temperature dropped in a day to the normal, and no further puncture was necessary.

It may be asked at this juncture how are we to know whether repeated puncture is necessary as indicated in a given case? If, after having punctured a patient in the manner which I have indicated, there is an improvement in the headache and the patient becomes rational, although the temperature continues to run a high or low course, we may wait a few days, and see whether the previous symptoms return, or whether the patient continues to improve. Following this plan, I have found that after a puncture the objective symptoms may improve as well as the subjective ones, but the tympanitic note continues over the ventricle. If the patient is to improve, this tympanitic note gradually disappears, the symptoms improve, and on convalescence we no longer get signs of fluid in the ventricles. If the patient, however, is so unfortunate as to continue after a slight remission of symptoms with the symptoms he had before puncture, we will find that not only do the percussion signs of hydrocephalus continue, but there is a deepening of the objective symptoms, such as sopor and hyperesthesia and rigidity, and this gives us our cue for our second puncture within twenty-four or forty-eight hours or more after the original puncture.

In this way we can do no harm if we are certain there is an excess of fluid in the ventricles. But, having relieved an acute hydrocephalus, if there is no return of symptoms, there is certainly nothing to be gained by a routine continuance of puncture in the face of improvement of the patient.

More difficult to treat are those cases which, in spite of repeated puncture, continue not only with the original symptoms of hydrocephalus, due to the reaccumulation of fluid, but in some cases, as we continue to puncture, the amount of fluid obtained diminishes with a diminution of the pressure, and in these cases we may attain to a point where there is little or no pressure at all as the fluid flows from the cannula. These cases are hopeless, because in them there is matting together of the parts at the base of the brain by exudate and a blocking up of the canals of Magendie and Mierjewski, preventing the fluid from the interior of the brain flowing into the subarachnoid space, thus into the subdural space of the cord, and externally. These are the cases in which lumbar puncture fails to obtain the therapeutic end that we seek; not only the relief of the patient but the cure of the disease.

In the first case mentioned in this paper it will be seen how lumbar puncture is really in the acute distension of the ventricles a life-saving operation. In some of these cases of acute cerebrospinal meningitis, if this great pressure continues, we can easily understand how the life of the patient may be threatened.

I have tried to mark out in this paper a scientific method by which all may approach the bedside, and in a given case, whether such a case is tuberculous or acute suppurative meningitis, determine definitely, first, that there is an increase of fluid in the ventricles of the brain; second, that this increase of fluid is causing pressure, and third, that this pressure can be definitely relieved, thus aiding the patient to tide over either a crisis in this disease, as in the acute forms of meningitis, or to enable the physician to make a diagnosis as to the nature of the meningitis in a doubtful case, as in the tuberculous forms of meningitis.

THE PROBLEM OF LOCALIZATION IN RELATION TO HEAD INJURIES.*

By WILLIAM W. GRAVES, M.D.,

ST. LOUIS, MO.

The problem of localization of lesions due to head injuries does not differ essentially from that which arises in other conditions (tumor, abscess, apoplexy, etc.), excepting in those cases in which consciousness is immediately or subsequently becomes so completely and permanently obtunded that the injured cannot be made to react to stimuli of any kind. In such cases localization can be accomplished only by relying upon the history since the injury and upon the oftentimes meager objective evidence.

Head injuries frequently give rise to the involvement of the brain at a point remote from the discernible injury to the soft parts, skull, and underlying structures; hence the determination, if possible, of the point or points of injury to the brain should be the first consideration, and this can be accomplished only by carefully eliciting and weighing the focal nervous symptoms present.

The necessity for operative interference may arise when either general or focal symptoms or a combination of these are present; and when focal symptoms are present, localization becomes at once of paramount importance. Under such circumstances localization forms the best guide to the surgical procedure, since it may point unmistakably to the seat of the lesion.

In order that focal symptoms may not be over-

*Read before the St. Louis Medical Society, March 24, 1906.

looked, it should be the rule that all head injuries, with or without visible fracture, with or without focal symptoms, giving rise to general symptoms indicative of increased intracranial pressure (disturbance in consciousness, headache, nausea, vomiting, stasis papillæ, alterations in pulse, respiration, and temperature) should be subjected to a searching neurological examination before operative interference.

Were this the rule, instead of the exception, which, unfortunately, still prevails, many lives might be saved that are now lost and many cases of post-traumatic paralysis, Jacksonian "fits," and other serious nervous phenomena might be prevented.

The sharp distinction between so-called *concussion* of the brain and *compression* of the brain so frequently found in surgical text-books and existing in the minds of many physicians and surgeons, is no doubt responsible, on the one hand, for nonsurgical interference in those cases in which concussion is diagnosed, and on the other, for absence of or insufficient surgical procedure in those cases of compression in which slight focal symptoms are overlooked.

The feeble resistance of nervous tissue to injury, and the certainty of its rapid destruction when deprived of adequate blood supply, resulting in permanent abolition or perversion of function, render it doubly incumbent upon both physician and surgeon to endeavor to localize the injury at the earliest possible moment and by surgical means to render it as inoccuous as possible.

In the light of our present knowledge of structure and function of the central nervous system and of improved methods in its examination, rendering localization at times a matter of almost mathematical certainty, and in the light of modern surgical technique, head injuries offer a field in which surgeon and neurologist may work shoulder to shoulder in the saving of life and in the prevention and alleviation of suffering.

Focal nervous symptoms due to head injury may develop immediately, gradually, or remotely after the injury. Focal symptoms may be due to involvement of the structures of the convexity, the base or intermediary brain substance—they may be due to cortical or subcortical lesions. The lesion giving rise to focal symptoms may be a contusion, or a laceration; it may be simple compression, by bone fragments, or by hemorrhage, blood clot, epidural, subdural, or subcortical.

It would far exceed the time limit of this paper to attempt to consider, even briefly, the topography of the brain and its bearing upon localization or to indicate the focal symptoms which might be expected to ensue from injuries involving different regions. The problem of localization in head injuries and the necessity for its solution can best be presented by a few case recitals.

Before referring to a recent personal observation, let me give two cases reported by Harvey Cushing.*

Case I.—"A young man was tilted out of the back seat of a wagon by the unexpected starting of the vehicle and landed upon the back of his head on the hard road. After some hours of unconsciousness he was found to have a homonymous hemianopsia and aphasia. Instead of investigating the cause of these symptoms, presumably due to local hemorrhages in the right occipital lobe, and, by contrecoup, in the left inferior frontal region, his physician, owing to the fact that there was neither a scalp wound nor any external evidence of fracture, and because the patient was making a progressive though slow improvement, decided against operation. Two months later there occurred an epileptic attack with a peculiar uncontrollable motor-speech (jargon) aura. These attacks increased in frequency and severity. Finally, a year later, the lower frontal convolutions were exposed, disclosing an adherent dura and a depressed scar over Broca's convolution. The epileptic attacks have ceased, but the visual defect and aphasia remain as before."

Case II.—"In the following case a different course was followed: A college boy sustained a severe blow on the head during a football scrimmage, and soon became unconscious. There was no indication of any external lesion. Though his symptoms had in large part subsided by the following day, he remained somewhat stuporous, responding slowly and reluctantly to inquiries. The movements of the face, tongue, and arm on the right side seemed somewhat less free than those of the corresponding parts on the opposite side, and when roused and questioned the patient stated his hand was 'numb.' Bloodstained fluid was found within the lumbar meninges. Through an intermuscular incision in the left temporal region a subdural clot, about a centimeter thick and covering the lower rolandic area, was bluntly scraped and irrigated away. The patient came out of the anesthetic with a perfectly clear and active sensorium, though with no memory of the events subsequent to the injury. His convalescence was rapid and he escaped the usual slow restoration to the normal—perhaps never quite to the normal—of these cases when left alone."

These cases need no comment. The lessons taught by them are obvious. They furthermore serve to emphasize the point made above that localization forms the best guide for surgical procedure since it may point unmistakably to the seat of the lesion.

A case recently seen in consultation with Dr. Willard Bartlett will serve to illustrate the immediate and gradually progressive development of general symptoms, the value of slight and easily overlooked localizing symptoms, and furthermore, that the injury to the brain may be remote from the visible injury to the soft parts.

Case III.—At 6 P.M., March 8, 1906, a previously healthy individual, aged 27, residing in Washington, Mo., received a sharp blow on the right side of head from the crank of a windlass. He was immediately rendered unconscious and his nose bled profusely for a while after the injury. In the course of about twenty minutes he was sufficiently revived to walk with assistance to his home, a distance of about 300 yards. He was immediately put to bed and a physician summoned, who found only a slight lacerated and contused wound in the right temple. The patient was dazed and drowsy, but could be easily aroused, and complained only of intense pain about right side of head. No evidence of motor weakness about face, tongue, or extremities; no bleeding from the ears; pulse and respiration increased but regular. Patient was very restless for several hours after the injury, vomited several times, and complained of great pain in head, but by the following morning this had ceased; he had now become more drowsy and could be aroused with difficulty. The tissues about both orbits had become swollen and discolored during the night, on the right more so than left.

Pulse and respiration were now slower than normal, but still regular. During the next twenty-four hours patient became stuporous, marked lessening in pulse and respiratory rate ensued, the former thirty and the latter ten to twelve per minute and irregular.

Bulletin of the Johns Hopkins Hospital, March, 1905.

The free administration of stimulants and injections of strychnia seemed to improve pulse and respiration somewhat and the stupor became less profound. No decided improvement occurring within the next few hours, the patient was brought to St. Anthony's Hospital, arriving there about sixty-five hours after the injury. He was seen shortly thereafter by Dr. Bartlett and myself and the following findings were noted: Sensorium greatly obtunded; reacts only when spoken to loudly and repeatedly and to painful stimuli and relapses immediately into stupor. Repeated commands to move arms or legs meet with no response, but protrudes tongue slightly, and this does not deviate. Pulse, 40, full and regular; respirations 14 and somewhat irregular; temperature normal. There is no difference in local temperature between the right and left sides of body. Tissues about orbits blackened and edematous; subconjunctival hemorrhage on right, none on left; bilateral chemosis; the eyeballs are in primary position, pupils are of medium dilation, right slightly larger than the left, both reacting to light in a normal manner. Facial innervation symmetrical. Both arms are in position of flexion and resting on chest and to passive movements show slight resistance, but no rigidities. There is likewise nothing suggestive about position of either upper extremity of a central lesion. The lower extremities also show no rigidities and no abnormal position excepting in this, that there is decided "foot drop" on the left. Pricking soles of feet with pin causes retraction of leg with extension of ankle on right, whereas on left the ankle remains in a flexed position. Typical Babinski and Oppenheim reflexes are present on left, absent on right. Knee jerk and Achilles jerk on right active; on left, knee jerk is absent and Achilles jerk much less than on opposite side. Radial and triceps reflexes absent on left, present on right; cremasteric reflexes equal; abdominal reflexes present on right, absent on left; respiratory movements less pronounced on left than on right. Examination of skull reveals a slight but infected lacerated and contused wound of right temple, with no evidence of fracture at this or any other part of skull as far as can be determined by palpation. Percussion discloses an area as large as the palm of hand extending an inch anterior to the rolandic area involving pretty generally the parietotemporal region, in which the percussion note is decidedly flatter than in the corresponding area on the opposite side or in the adjacent areas on the same side.

A consideration of the history since the injury, which was to the effect that following a brief period of unconsciousness the patient was able, with assistance, to walk to his home; that he was restless for several hours, during which time vomiting occurred; that the restlessness gave way to somnolence, and this to stupor, with increasing diminution in pulse and respiratory rate, could lead to but one conclusion—that a gradual compression of the brain had developed since the injury, and that this was probably due to hemorrhage. The profound disturbance in patient's sensorium, the absence of discernible injury to the skull, and the absence of palpable focal symptoms made it necessary to depend wholly upon the objective findings for a localizing diagnosis. The difference in the size of the pupils' right greater than left; diminished respiratory excursions on left; absence of abdominal reflexes on left; the presence of Oppenheim's and Babinski's reflexes and the presence of "foot drop" on left pointed conclusively to an involvement of the motor tracts in the right hemisphere. The absence of seventh and twelfth nerve involvement practically excluded, and extensive subcortical or capsular involvement of these tracts, and at the same time indicated that the lesion involved the convexity and at a point above the lower rolandic area. Thus a consideration of the history and the focal nervous symptoms made it highly probable that a hemorrhage either epidural or subdural involving the right rolandic area was responsible for the focal symptoms present. The additional evidence obtained by skull percussion strongly supported this conclusion and rendered the localization practically certain.

The patient was immediately placed upon the table and prepared for operation. Dr. Bartlett made the usual incision, and on reflecting the scalp the exposed area of the skull showed a normal condition. The skull was opened at a point just beneath the wound of scalp, or at a point corresponding to the middle third of the second frontal convolution. Neither epidural nor subdural hemorrhage was found at this point, but the exposed area of the brain manifested evidence of increased intracranial pressure. The opening was enlarged in all directions, especially posteriorly, when, as the Rolandic fissure was encroached upon, epidural clots were extruded in considerable number; enlarging the opening still further backward and downward enabled the operator to thoroughly remove the extravasated blood. The dura had not been lacerated. The separation of the dura from the skull had occurred somewhat toward the vertex, especially posteriorly, and toward the base extending in this direction downward into the middle fossa. There was found a fracture involving the parietal bone beneath the squamous portion of the temporal bone, and several fragments were removed. The wound was closed, but a light gauze pack was left in the epidural space extending downward in the direction of the middle fossa to control possible secondary hemorrhage. Before the patient left the operating table the pulse and respiration had become nearly normal. Consciousness was regained four hours after the completion of operation, when it was ascertained that the patient had no recollection of events since the morning following the injury. The patient has made an uninterrupted recovery. He was for the first week somewhat somnolent, but was readily aroused, and was then always fully conscious of his surroundings. Two days after the operation the "foot drop" had entirely disappeared; the knee jerk had returned on the left, and the tendon reflexes of the right lower extremity, while no longer active, were slightly stronger than on the left. Abdominal reflexes were now present on both sides and equal, the respiratory excursions were equal on the two sides, and Babinski and Oppenheim reflexes had disappeared. A sensory examination made at this time showed slightly diminished pain and tactile perceptions of the entire left side of the body with no disturbance in posture and stereognostic senses. Four days after operation even this slight sensory disturbance had disappeared, and as far as can be determined patient's nervous system is now (March 24, 1906) normal.

I have reported this case rather at length, because it seemed to elucidate in an instructive manner the problem of localization and the necessity for, and the possibility of, its solution in head injuries.

In conclusion it may be stated that a satisfactory solution of the problem of localization in traumatic lesions of the brain will depend upon: (1) A consideration of all symptoms and their order of development since the injury; (2) the degree of consciousness manifested by the patient and his

reactions to stimuli; (3) a degree of involvement of areas of the brain of known function sufficient to cause focal symptoms; (4) the carefulness and thoroughness with which the examination is made.

THE SURGICAL TREATMENT OF TRIGEMINAL NEURALGIA.*

A STUDY OF THE CAUSES OF RECURRENCES AFTER OPERATIVE TREATMENT, WITH SUGGESTIONS AS TO THE BEST METHODS OF OBVIATING POST-OPERATIVE RECURRENCES.

LEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK.

ADJUNCT ATTENDING SURGEON, MOUNT SINAI HOSPITAL.

In order to understand the various methods that have been devised in the treatment of trigeminal neuralgia, a short review of the pathogenesis is necessary. Despite the fact that the pathology of trigeminal neuralgia has been so extensively studied, there is no agreement in the views of the numerous observers. The changes that have been found may be classified under two headings, first, those that have been found in the peripheral nerves, and secondly, those that have been found in the Gasserian ganglion.

The pathological changes in the peripheral nerves.—Dana[1] found an obliterating endarteritis, but no changes whatever in the nerve elements. Putnam[2] in ten cases found as the most frequent pathological change an endarteritis and a general fibrosis. Horsley[3] found an increase in the fibrous tissue content of the nerve, or what is generally termed a sclerosis, which he attributes to a chronic inflammatory process. In a subsequent communication,[4] however, he finds that in every instance the epineurium is shrunken and sclerosed; he also qualifies this statement by attributing his findings to the long duration of the disease in his cases, and suspects that, had the patients been operated in their earlier stages, an active congestion and edema might have been found. He finds an endarteritis in some cases, but not in others. Schweinitz and W. Rose (quoted by Krause) found in addition to an obliterating endarteritis, that the axis cylinders appeared either swollen or shrunken, and occasionally absent; the myelin sheaths were swollen and showed on cross section a number of indistinct concentric rings; the sheaths of Schwann appeared shrunken and markedly rich in nuclei. The endoneurium was increased, particularly in the neighborhood of the blood-vessels. The changes resembled those of a chronic neuritis, and as they were more marked in the periphery than in the center, Rose assumed that the lesion was an ascending one. Krause's[5] examinations of nerve trunks, obtained by the evulsion method of Thiersch, showed only occasionally a thickening of the nerve sheaths, and nothing else.

The pathological changes that have been found in the Gasserian ganglion.—Schuh (quoted by Krause) examined the ganglion, obtained at autopsy, from a patient who died of pyemia, the result of a resection of the inferior dental nerve, and found a pigmentation of the ganglionic cells; the ganglion itself was swollen and the vessels turgescent with blood; so that he assumes an exudative inflammation. (The findings in this case cannot be regarded as valid, because they may have been due to an extension of the inflammation from the suppurating focus.) Rose (quoted by Krause) found in his first case of extirpation of the ganglion a thickening of the interstitial connective tissue and irregularity in form of the ganglionic cells; on the basis of these findings he regards the disease as a chronic inflammatory process, resulting in contraction and compression of the nerve cells. Horsley[4] says that he has not seen more degenerative changes in the ganglion than could be accounted for by the age, condition, and habits of the patient; in three cases, however, he found both the ganglion and roots firmly matted by adhesions to the walls of the cavum Meckelii. Antonio d'Antona (quoted by Krause) merely found a sclerosis of the ganglion. Krause,[5] in an examination of a large number of cases, found no sclerosis or endarteritis, but only a degeneration of the ganglionic cells and nerve fibers. He concludes his remarks by saying that whatever the pathological changes may be, the origin of the disease must be in the Gasserian ganglion, because recurrences did not take place in any of his cases of complete extirpation of this organ, particularly as, in some cases, three and one-half years had elapsed since the operation. Inasmuch, however, as Krause himself in a subsequent communication[6] reports two recurrences, this statement requires qualification. Furthermore, if this view of Krause is correct, how can he account for the benefits, if sometimes only temporary, that are obtained by peripheral operations? Also, how can he explain the almost complete immunity of the ophthalmic division? In this connection it may be remarked that some observers have held that the disease originates in the sensory root of the fifth nerve; were this the case, we should also expect involvement of all three branches, which only rarely occurs.

The argument of many observers that the disease is a neuritis can probably be negatived; with the exception of the symptom of pain, trigeminal neuralgia presents none of the symptoms and physical signs of any of the other well-recognized neuritides, such as anesthesia, paralysis, or the electric reactions.

Davis[7] examined a ganglion by the Nissl method of staining, and describes his findings in the following words: "There are a large number of cells of normal contour and staining properties. There are also, however, a large number of cells in advanced state of degeneration, irregular in outline, with a peripheral position of the nucleus, which is also at times irregular in outline, and containing at one end of the cell considerable masses of yellow pigment. There are other cells in which the nucleus has entirely disappeared. These cells stain a deep purple by the Nissl method. A few cells, while irregular in outline and appearance, take the stain very faintly. There are several empty capsules, caused evidently by a complete disappearance of the cells. By the hematoxylin eosin stain the above results are confirmed. The capsules of the degenerated cells are irregular in outline and show a tendency to collapse, when the degeneration is very advanced. Many concentric calcareous bodies are seen among the nerve fibers and in the stroma of the distal end of the ganglion. By the Weigert sheath method the pigment in the ganglionic cells looks of a dark brown, almost black, color." Frazier[8] says: "Not a great deal is known of this (pathology) phase of trigeminal neuralgia. But from our present knowledge it can be safely asserted that there are two or three distinct types of trigeminal neuralgia—one, in which the lesion is primarily a neuritis of the peripheral branches, which subsequently may or may not extend to and invade the ganglion; the other, in which the primary lesion first appears in the gan-

*Read by invitation at a meeting of the New York Neurological Society, May 1, 1906.

glion; and a third, perhaps, in which the lesion is neither in the ganglion nor in its branches, but in the central nervous system. The lesion may be of a degenerative type, an intestitial neuritis, or a neoplasm." Spiller,[9] who has examined ten Gasserian ganglia removed by Keen, describes his findings as follows: "The lesions in the Gasserian ganglion in the more advanced cases of tic douloureux consist of much swollen medullary sheaths, swollen axis cylinders, atrophied fibers, empty nerve sheaths, nerve bundles in which the nerve elements have been destroyed and only connective tissue is left, atrophied ganglion cells, cells faintly stained, and sclerosed blood-vessels, in some cases even without a lumen."

All the observers quoted above have regarded the pathological changes as primary and in direct etiological relation to the disease. Assuming even that many of the changes which they describe have actually occurred, we cannot accept their findings as primary, because all the pathological changes can be easily accounted for as secondary products. These secondary influences might be classified as follows: (1) Rough handling of the nerve or ganglion as the result of the necessary manipulations in the course of the extirpation. (2) Incomplete preservation of the ganglion after removal. (3) The age of the patient. As is well known, the disease occurs mostly in patients past middle life, in whom endarteritic and sclerotic changes are very prone to occur. (4) Ascending changes in the nerve or ganglion as the result of previous peripheral operations. That this possibility has been well appreciated by investigators is revealed in the researches of Monari,[10] Schwab,[11] and Coenen.[12] In order to exclude this possibility these observers report the examination of five ganglia, in cases where no previous peripheral operation had been performed. It is significant that these five ganglia were found to be entirely normal.

As opposed to the positive findings of the above authors, Billroth, among the earlier observers, and Hutchinson and Cushing in more recent times, found no changes in the ganglion or nerve whatever. In the words of Cushing, no lesion sufficiently characteristic to consider it typical of a particular disease is present.

It cannot be denied that occasionally gross pathological changes, as sarcomata, fibromata, neuromata, psammomata, cholesteatomata, etc., either of the ganglion or nerves, or of adjacent structures, have been found, and with a mistaken diagnosis the Gasserian ganglion has been extirpated, but these do not properly come into consideration, inasmuch as they are not true cases of neuarlgia.

I do not like to sumbit any theory that cannot be proved by definite pathological or physiological evidence, but it has occurred to me, whether trigeminal neuralgia cannot be accounted for by assuming some variety of vasomotor disturbance; it might therefore be classified with such diseases as Reynaud's disease, intermittent claudication of Erb, erythromelalgia, etc. There are a few clinical data that are common to both; the intermittent character of the pain, the age of the patient, and the relief which is often obtained by the administration of such drugs as nitroglycerin or aconite (vasodilators), or strychnine (vasoconstrictor).

As I have indicated, we know practically nothing of either the etiology or pathology, or even the site where trigeminal neuralgia originates. This is unfortunate, because it prevents us from attacking the disease in a rational manner, and compels us to treat the neuralgia on a purely symptomatic basis; as I shall show, that even the most radical operation, the extirpation of the Gasserian ganglion, can only be regarded as a symptomatic cure.

The treatment of trigeminal neuralgia having resolved itself to the relief of pain, the simplest operation that can be devised would be one which prevents sensory impulses from passing to the brain; in other words, a neurotomy. In recording the evolution of the various operations for trigeminal neuralgia, we find, in fact, that neurotomy was the first operation that was performed. This was done as early as 1748 by Schlichting. Similar operations followed by Louis in 1766 and Viellart in 1768. The immediate results were very good, but as was to be expected, they were followed by relapses in short order. These recurrences were evidently the result of regeneration and reunion of the divided nerve.

It was therefore merely a short step to the next operation, which consisted in the extirpation or resection of as large a segment of the nerve as could be exposed by the operation; in other words, a neurectomy was performed. This operation, however, was also followed by disappointment, inasmuch as constant recurrences took place, although they ensued at a later interval than after simple division. While this operation is even now performed occasionally by some surgeons, we find that as early as 1845 Dieffenbach had already condemned the operation in his work on operative surgery.

No material progress was made for several decades. Acting upon the assumption that the operations hitherto performed failed because they were done too near the peripheral distributions, surgeons next turned their attention to the more centrally located portions of the fifth nerve; namely, at their exit through the foramina at the base of the skull.

Technically correct operations have been devised for the division of the second branch by Carnochan, by Luecke,[13] and subsequently in a slightly modified form by Lossen,[14] and by Braun;[15] other methods for reaching the second branch are the operations described by Gussenbauer[16] and Friedlander.[17] For the exposure of the third branch extracranially Kroenlein[18] has devised an excellent and much practised method; other methods have been described by Kocher[19] and Mikulitz-Madelung.[20] The second and third branches together may be reached by a method devised also by Kroenlein.[21 22] That all of these operations are technically feasible is proven by the fact that all have been performed with greater or lesser frequency; at the same time it cannot be denied that they are difficult of execution; the space afforded, even after resection of the zygomatic arch and extirpation of the coronoid process of the inferior maxilla, is a very limited one; the wound itself is very deep, and filled with adipose tissue and large vessels, and the hemorrhage, though controllable, is sometimes very severe. Excluding, however, the technical difficulties, these operations have been found wanting because of the frequency of recurrence of the malady in a large percentage of cases; and just as in neurotomy and neurectomy, the cause of the relapse in the cases examined has in every instance been due to a regeneration of the divided nerve. As a matter of fact, if critically analyzed, these operations at the base of the skull are merely neurotomies and neurectomies, which have simply been performed at a higher level; so that the reported relapses are not at all to be surprised at.

The next step in the evolution of the treatment of trigeminal neuralgia was in some respects a recourse to the older operation of neurectomy. The occasional (though few) fatalities, and especially the

large percentage of relapses after the major infracranial operations, again led the attention of Thiersch to the peripheral distribution of the fifth nerve, and in 1889[23] he came forward with his method of evulsion (neurexairesis) of the nerve.

The method is so well known that it hardly needs a lengthy description; suffice it to say that the affected nerve is exposed through a small incision, usually at the periphery, at its exit from one of the foramina. It is then firmly grasped by forceps, especially constructed for the purpose, and slowly, utilizing at least half a minute for one turn of the forceps, the proximal and distal portions of the nerve are twisted, until both tear off. Usually the proximal portion gives way first, very probably because the nerve breaks over the edge of a deeper foramen; the distal portion can be evulsed to a greater length, so that practically the entire peripheral portion, to its finest endings, is evulsed. In this manner beautiful anatomical specimens, eight to ten cm. or more in length, can be obtained.

This method marked a great step in the treatment of trigeminal neuralgia. As might be expected, the immediate effects were excellent, and the earlier reports speak of it with enthusiasm. After the patients, however, had been observed for a sufficient length of time, there appeared the reports of recurrences, which increased in frequency, as sufficient time is allowed to elapse after the operation. In his very first communication Thiersch already describes a recurrence of supraorbital neuralgia, which, however, he ascribes to some anatomical abnormality; he argues that a regeneration of 6 cm. of nerve tissue cannot be conceived; it is more than probable, however, that his very first case of recurrence was due to regeneration, as subsequent recorded cases have proven.

Angerer,[24] for instance, records a goodly percentage of recurrences after nerve evulsions, but ascribes these to a faulty technique. There is no necessity, however, to quote lengthy statistics of recurrences after the Thiersch operation; they are well known, probably, to all of you; I also have seen a number.

The poor results obtained by the peripheral operations that I have described led surgeons to the idea of attacking the intracranial portion of the fifth nerve. Mears[25] suggested the operation in 1884, but never had the opportunity to perform it. As far as I can ascertain, the first intracranial operation was performed by Rose,[26] who extirpated the ganglion; he chose the pterygoid route for its exposure. Shortly thereafter Horsley, in 1891, divided intracranially the roots of the fifth nerve. I may add here that this operation has again been warmly advocated by Spiller and Frazier;[27] it has also been performed by Keen, and, according to von Gehuchten,[28] by Lauvers in three cases.

Ganglionic extirpation was, however, placed on a firm footing only when it was accurately described and performed by Hartley,[29] and independently by Krause.[30] Since then the technique of the operation has been modified by various observers, notably by Cushing,[31] who suggests the transzygomatic route; by Hutchinson,[32] who performs only a partial extirpation of the ganglion, leaving the infrequently affected first division, for the reason that its removal is fraught with such dangers to the eye; by Rose, who performs a high section of the roots of the fifth nerve, and by numerous French observers, who report complicated methods of attack. The underlying principle in all these operations is, however, the same, namely, that the Gasserian ganglion is extirpated, after division of its branches.

After this operation the number of recurrences suddenly diminished. No one can, however, deny that this has been dearly bought; the operation is one of the most severe that surgeons can perform, and is attended by a comparatively high mortality. Thus Tiffany[33] has collected 108 cases of the operation, with 22 per cent. mortality; Turk,[34] in a later series, reports a mortality of 17 per cent. in all the collected cases. This is not surprising when we consider the deep location of the Gasserian ganglion, the important and delicate surrounding structures, which are exposed to much handling in the course of the operation, *e.g.* the meninges, the brain, the cavernous sinus, etc. Death seems to have been due in most of the fatal cases either to infection, or hemorrhage, or shock.

The results in the very large percentage of operative recoveries are excellent; we must acknowledge, however, that even this severe operation has been attended by undoubted instances of recurrences. Such are reported by Friedrich,[35] Garre,[36] Parmenter,[37] Sapejko,[38] Schwartz,[39] Marchant and Hebert,[40] and Perthes.[41] To these might safely be added also two cases of Krause[42] of distinct and undoubted relapse, though the author ascribes the recurrence in the one case to hysteria, and in the other to a neuralgia of central origin. That there are many recurrences after incomplete extirpation of the Gasserian ganglion is not surprising. If it is furthermore considered that many of the cases are reported after a very short period of observation (in some instances less than two weeks), we cannot but believe that a report after a much longer period of observation would swell the list materially.

With the demonstration of this appreciable list of undoubted recurrences after complete extirpation of the Gasserian ganglion, we cannot but believe that the operation is not based on correct principle. Even one authentic case, such, for instance, as that of Perthes, in which Marchand performed the autopsy, is sufficient to invalidate the operation. We are bound, therefore, to come to the following conclusions regarding the Hartley-Krause operation: (1) The operation is attended by a very high mortality; (2) it undoubtedly gives the greatest number of complete recoveries; (3) occasional, though rare, recurrences have been met with after this operation, even in competent hands; (4) the relapses are due to a regeneration and reunion of the divided nerves.

In summing up the results of the operative treatment of trigeminal neuralgia, as I have outlined it, we find that in all cases of recurrence this has been due to a regeneration of the divided or extirpated portions of the nerve. It is not within my province to discuss here the causes and process of regeneration; nor is it of great importance for the purposes of my paper to take sides in the question, whether the nerve regenerates from the central or from the distal end, or from both; the important point to realize is that it does regenerate; this I believe I have amply proven by the cases cited, and have demonstrated it to my own satisfaction in cases of my own. (Those interested will find a complete résumé of the question in Schütte's article in the *Zentralblatt für Allgemeine Pathologie,* 1904, Vol. XV, p. 917.)

I lay no claim to the discovery of this principle, as subsequent search of the literature has taught me; the principle was, however, brought home to me in a striking fashion in a case which I shall now describe.

The case was one of severe neuralgia of the inferior dental nerve. I operated upon the patient

in the following manner: An incision one inch in length was made, extending from the angle of the jaw forward; the masseter and periosteum were separated from the ascending ramus and retracted upward; with a narrow gauge, a groove was now chiseled into the ascending ramus, until the inferior dental canal was exposed for a distance of about one inch. The inferior dental nerve was carefully isolated from the accompanying vessels, and one and one-quarter inches were resected. The masseter and periosteum were replaced and fastened by sutures, and the skin closed. Primary union followed, and patient was discharged, free from pain.

One year later patient presented himself at the hospital, with a recurrence of pain, which was quite as severe as before. I reopened the old cicatrix, and after retracting the masseter upward, found the groove in the external surface of the ascending ramus of the lower jaw, with smooth, rounded edges and filled by cicatricial tissue. Within the canal I exposed distinctly a newly-formed inferior dental nerve of normal appearance. I again extirpated about one and one-half inches of the nerve, and with the idea of preventing regeneration I filled the canal with silver foil and hammered it in until it was tightly packed. Again I sutured the masseter into place, and closed the skin incision. The silver foil remained *in situ*, and has remained there ever since; the patient up to the present time—ten months—has been free from recurrence.

Some two weeks after this operation, I received a number of the *Deutsche Zeitschrift für Chirurgie*, containing an article on trigeminal neuralgia by Perthes,[41] already referred to. There was a short appendix to this article, which was of the greatest interest to me. This appendix dealt with an experiment which Perthes carried out on a large dog. Upon the left side he exposed the infraorbital nerve and evulsed by the Thiersch method 9.5 cm. of the nerve. Upon the right side he divided the nerve at the foramen, and had Dr. Fritzsche, a dentist, plug the foramen with gold. Seven months later the dog was killed, and at autopsy the following condition was found: Upon the left, *i.e.* upon the side on which the nerve was evulsed, a newly-formed, complete nerve was found; upon the right side the filling was found intact, and naturally there was no union between the divided ends of the nerve. I saw, therefore, that experimentally, at all events, I was antedated by Perthes.

The principle (which I thought I had discovered) had also been made use of by Abbe,[43 44] who interposed a piece of rubber tissue between the intracranially divided ends of the second and third divisions of the nerve. I regard this operation as the only intracranial operation that is founded on correct principle. Hutchinson[32] devotes considerable space to arguments against this operation. The arguments advanced by Hutchinson I regard, however, as superficial and based on fallacious theories as to the cause of recurrence after removal of the Gasserian ganglion.

I would not, however, defend the Abbe operation in its entirety. I believe the weak part of the operation consists in the use of rubber tissue as an intervening medium. It is too soft and yielding to be accurately handled, and, furthermore, I believe that by the action of phagocytosis it may crumble and disintegrate in time, and even disappear, thereby enabling the nerves to regenerate. A more suitable substance would be fine celluloid, such as is used in photographic films. I have also had made thin, flat gold buttons, provided with suitably sized shanks, which can easily be inserted into the foramina. I have had no occasion to use either of these appliances, but shall do so at my earliest opportunity.

Among other suggestions that have been advanced by some surgeons may be mentioned those of Morse,[45] who advised Horsley's bone wax, and Chippault, who suggested the use of dentist's amalgam.

I cannot conclude a review of the operative treatment of trigeminal neuralgia without referring to the intraneural injections of osmic acid, which have been so warmly advocated by Murphy. There is no doubt that this operation gives temporary relief, but I believe that in the great majority of cases a recurrence follows sooner or later. A very thorough clinical and experimental study of this procedure has recently been published by Eastman.[46] He found that pathologically the injected nerve was in no way affected by the osmic acid injections, and that therefore he could not see why the neuralgia should not always recur. He admits clinical recurrences, and states that the operation will probably have to be repeated over and over again.

Conclusions.—I believe the treatment of trigeminal neuralgia may be summed up as follows:

1. Eliminate any possible etiological factors, such as tumors, carious teeth, antral disease, malaria, syphilis, etc.

2. Determine accurately the nerve branch or branches involved.

3. The operation should be performed as near to the periphery as possible.

4. The operation should be performed early. This is important, because the earlier the case, the more chances there are that a peripheral operation will be of benefit.

5. Whatever the character of the operation may be, the dominant principle must be the *prevention of regeneration* of the affected nerve. More specifically, the operations may be classed under two headings, depending on the nerve or nerves affected:

(a) Peripheral operations. If the supraorbital, infraorbital, mental, malar, or inferior dental branches, either singly or collectively are involved, the operation consists in division of the nerve, and plugging up of the foramen by a gold or silver button or wire.

(b) Central operations. If the neuralgia involves the upper teeth and palate (superior maxillary division) or tongue (inferior maxillary division), existing either singly or together with the other nerves described above, the operation as outlined by Abbe must always be performed, substituting, however, celluloid or a gold button, instead of rubber tissue.

6. Finally, I believe that if the above principles of treatment of trigeminal neuralgia are carried out, the operation of extirpation of the Gasserian ganglion will become entirely unnecessary.

ONE HUNDRED AND THREE CASES OF EPILEPSY.

By WILLIAM L. STOWELL, M.D.,

NEW YORK.

Epileptics suffer a temporary suspension of consciousness, recurring at intervals, usually accompanied by muscular spasms, and followed by stupor.

The above statement is my definition of the disease. It is estimated that there are 150,000 epileptics in the United States. This large army of afflicted persons may well occupy our attention for a time. Of that number, I have notes upon 103 cases in private practice, dispensary, and hospital.

Age.—The young are most affected. Of 1,700 patients treated at the New York University Children's Clinic, eighteen cases were epilepsy, *i.e.* about one per cent. The youngest began at two weeks of age, and others at three months, four months, seven months and eleven months, and then at practically all ages. Thirty-nine cases began under five years, sixteen between five and ten years. Of my one hundred and three cases, eight are recorded as being five years of age when seen, thirty-one between five and ten years, fifty-two between ten and twenty years, and twelve over twenty years of age.

As thirty-nine cases began under five years of age, and sixty-three are under treatment at four times that age, it is apparent that epilepsy has little tendency to shorten life or to be readily cured. It is found that children of uncertain nervous equilibrium are most easily subject to convulsions. At the periods of dentition and puberty such a child is prone to convulsions if there be indigestion, or any acute disease developing. This is true also of women at the menstrual period. A series of spasms having begun, the nerves readily acquire the convulsive habit, and what was at first a group of symptoms becomes a disease.

Heredity.—Children of unhealthy or neurotic parents are more liable to become epileptic than are those of perfect ancestry. The following cases are cited as examples: Case iii., brother insane; case x., mother paralyzed; case xvi., parents moderate drinkers; case xx., mother epileptic; case xxxi., parents heavy drinkers; case xxxix., mother hysterical, father intemperate, uncle and two aunts very nervous; case xiv., father intemperate; case liv., father intemperate, and mother suffered from neuralgia for years; case lxvii., father phthisical; case lxxxvi., girl of eight years, spasms since four years old, seems hysterical, mother had convulsions, and so had two brothers at dentition, another died at eight days old of convulsions; case xc., had fits from fourteen years to death at twenty-eight years; during a fit she overturned a table and lamp, which so burned her that death resulted in a few hours. She left two children, one five years old, who is very nervous, but as yet has not developed any convulsions.

Many of the hospital cases have little or no family history, but they originate in a class of people used to poverty, overcrowding, and the abuse of alcohol. These evils cause bad heredity and injurious environment, which in their turn produce ill-conditioned bodies and impoverished nerves. Though convulsions cannot be directly inherited, a good preparation for them can be transmitted. Forty-nine per cent. of the children of epileptics become epileptic. This should be remembered when we are asked whether epileptics should marry or not. Spratling states that sixteen per cent. of epileptics have epileptic parents, fifteen per cent. have alcoholic parents, and that tuberculous heredity is found in fourteen per cent. of the cases. He also finds that the more unfavorable the hereditary combinations the earlier the age at which epileptic seizures begin. Cerebral palsies he finds to be the cause in eleven per cent. of his cases, and one-third of these are congenital.

Palsies appear in twenty-two of my cases, as follows: Left hemiplegia, 5; right hemiplegia, 15; left upper extremity, 1; right upper extremity, 1.

Direct Causes.—The immediate cause of the first convulsion may arise in many ways. For example, we find fright from swinging; fright from fire; burn from hot oil on the shoulder; in four cases from falling down stairs; fall from fourth story; fall of sixty-two feet when two years old; injury at birth—instrumental delivery, but no fit until ten years old (?); masturbation—also a questionable cause; phimosis; two cases of traumatic meningitis; beam falling on skull; cold steamed current dumpling at one year old; in two cases, run over by wagons; one knocked down by horse, which stepped on forehead; measles; scarlatina with dropsy; pertussis; sunstroke; eating oranges at seven months of age—

convulsions for four and a half hours; first fit due to green apples; another, fright in a three-year-old child. A case of peculiar interest was No. lxxi.—a girl of twelve years, whose first fit occurred when she was eleven months of age. Her mother nursed her just after receiving news of the sudden death of an older child. The shock so affected the milk that it gave the baby convulsions, which continued for four days, and were followed by facial paralysis for one week. Spratling finds 6½ per cent. caused by trauma, while the present series contains fourteen cases so caused.

Types.—Epilepsy is spoken of as "mild" or "severe" in form; or, more commonly, as *petit mal*, or *grand mal*. Of this series, fifty-three cases are recorded as *grand mal*, thirty as *petit mal*, and thirteen as mixed—some of the latter being in both the mild and severe column. In addition to these are examples of peculiar phases less commonly seen. Gowers finds one-third of the cases of psychic origin. The following fourteen are largely psychic in manifestation.

Peculiar Phases.—Case xv., violent temper, fighter, no cause; case xvi., violent temper; case xviii., barks and shrieks in attacks. (These are the cases that gave the ancients excuse for ascribing the disease to the malice of demons.) Case xxx., status epilepticus every three months, did not speak for six weeks, thought to be tongue tied; case lxviii, also status epilepticus every three months; case xxiv., wild delirium and dancing, contortions; case lxiv., amnesia, twice a year, lasts two weeks, wanders aimlessly for hours, like one coming out from delirium; case xliv., insane? case xlv., became insane—sent to Ward's Island; case liii. (1904), curses, bites himself, wild in talk and actions, (1906) idiotic; case lx., girl runs about suddenly, instead of having fit; case lxxxii., girl talks during attack; case xcii., screams, stands, has no idea of time, now *petit mal*, formerly *grand mal;* case c., runs, cries, does not fall, cause said to be fright; case ciii., boy eleven years old has periods of twenty-four to forty-eight hours during which he does not know what he does or what occurs; sometimes ends in a cataleptic coma; he was lost for a week two and a half years ago and was nearly starved; there is some question as to whether this was the cause of the spells or simply a prolonged attack; he has an epileptic sister.

Premonitory Symptoms.—Many epileptics experience some sensation which is a warning that an attack will shortly take place. This aura, or breath, is most common in cases of eccentric origin—Jacksonian. As the aura is the last record of consciousness, there will be no recollection of the fit in those without it. The warning gives to many time to save themselves from injury. This sensation may be peripheral, or it may arise in the special senses. Examples are as follows: From the scar of a burn; four have peculiar feelings in the stomach; five have headache; three have vertigo; a feeling of fear; pins and needles in the chin; machinery in paralyzed arm; peculiar smell and taste; feels like yelling; peculiar odor; peculiar sensation in the nose; shock goes through body, and patient fears that the ceiling will fall; sensation in the chest; swears violently; mental excitement; sudden feeling that all seen or heard has appeared before. The taste sensation is apparently rare. Sachs, in particular, mentions not having seen such a case.

Insanity and epilepsy are closely related or allied. 8.6 per cent. of the insane being epileptic (Allbut, viii., p. 335). Case xxxi.—A boy of fifteen years had from twenty to thirty fits a month; but once in six months would seem to be insane for a few days instead of having convulsions; in March, 1905, he had appendicitis and was operated upon; the appendicitis was cured, but the epilepsy remained as before. Case xliv.—A boy of twelve years; appears insane at times. Case xlv.—A boy of nineteen years; became definitely insane, and was sent to Ward's Island. Three per cent., therefore, is the proportion of insanity in this series.

The relation of the two diseases and the hereditary tendencies of each are full of interest, but my numbers are too small for conclusions. Gowers asserts that there is a family history of epilepsy in 66 per cent. of his epileptics, and a history of insanity in 33 per cent. of them. Repeated epileptic seizures must produce a profound effect on the brain, yet the mind is not always dulled. Mentality is recorded as good in twenty-six cases, fair in five, normal in three, while thirty-three cases are imbecile.

The children seen at the clinic were nearly normal mentally, while those in the hospital, being more severe or of longer standing, were of a lower mental grade. There are historic cases of epileptics noted for intellectual power, Julius Cæsar, Mahomet, and Napoleon Bonaparte being well known instances.

Anatomy of Epilepsy.—Hughlings Jackson divides the nervous system into three layers—(1) Lowest: Marshall Hall's spinal system, control of walking, respiration, etc.; (2) Middle: "Functionally definite, but anatomically not so readily definable;" corpus striatum, sensorimotor in character; (3) Highest: Intellectual centers—"organ of mind"—less automatic. Here are the psychic forms, periods of blankness, etc.—(Spratling: p. 105).

Physiology of Cause.—"Formerly nerve cells were thought to be the source of energy. Now, histologists teach that the function of the nerve cells is nutritional. We must regard the spongy gray matter as the source of nerve energy. In this arise the fibers that become axis cylinders. Impulses of health or disturbances of disease start here. They travel through the fibers, which traverse nerve cells, and then through efferent nerves reach muscle fibers, thus bringing about voluntary action, or causing spasm." Gowers says (Allbut's System of Medicine, vol. vii., p. 762) that we know nothing of the pathological anatomy of idiopathic epilepsy. "Any perceptible alterations are more likely to be the result of functional disturbance rather than the cause of it." He regards epilepsy as due to diminished resistance of inhibitory fibers in the spongy gray matter, the fault of the "neurous of association" rather than of the cells themselves. Hughlings Jackson regards the disease as one with increased nutrition, causing exalted function and strong discharges. Marinesco and Serieux give three specific lesions—(a) Partial disappearance of tangential fibers of the cortex, *i. e.* the "neurons of association;" (b) Infiltration of nerve cells by leucocytes; (c) Disappearance of the fine granules in the cell substance of cortical nerve cells (chromatolysis).

Responsibility for Crime.—Persons having psychic epilepsy, or the psychic equivalent of a seizure, sometimes commit offences which render them liable to be classed as criminals or insane. It is difficult to draw the line. This is the "Comitial ambulatory automatism" of Jones.

Treatment.—Having learned that the epileptic has an irritable nervous system, an unstable cortex, we try to improve general nutrition and quiet the nerve cells. A vegetable diet is advocated, with all that makes for good hygiene. Of drugs, seventy-

five are listed as good; the last one advocated is suprarenal extract. Epileptic children should not attend public schools, but should be taught where there is little strain and excitement—manual training there may be, but with a care about edged tools. No drugs stand the test of time like the bromides. If the patient is deprived of ordinary salt in his food, larger amounts of bromides can be tolerated, and do good. As intestinal disturbances provoke attacks, this part of the anatomy must be watched. The bromides, with general tonics, has been my plan of treatment almost always.

Surgery and Epilepsy.—Two of the cases were operated on for appendicitis, one had a double ovariotomy, and one was circumcised. Four were subjected to craniectomy—two because of injury to the skull from falls, one because of depressions owing to a falling beam, one for symptomatic reasons. There does not seem to have been any permanent or material relief. Usually a new scar is substituted for an old one. Pressure from traumatism must be relieved by immediate action after the accident, and not after fits have been established. Sachs says: "Our ardent hopes in this matter have not been realized." Jacobi's verdict is "Not dangerous, but inefficient."

Care of the Patient.—The proper care and treatment for epileptics is to be found in colonies like that established in Westphalia thirty-five years ago. There 6½ per cent. are cured and 20 per cent. are improved. Ohio, Pennsylvania, California, New Jersey, Massachusetts, and New York now have such colonies, ours being the well known Craig Colony at Sonyea.

Prognosis.—The less the hereditary influence the better the prognosis. The fewer the fits at night, the better the outlook.

Jacobi says: "The spasms and convulsions of infancy are serious manifestations, and if allowed to go unchecked may lead to explosions of genuine epilepsy, and later to insanity."

A PLEA FOR A MORE THOROUGH COURSE IN PRACTICAL PHARMACY IN OUR MEDICAL SCHOOLS.

By M. CLAYTON THRUSH, Ph.M., M.D.,

PHILADELPHIA.

INSTRUCTOR IN PHARMACOLOGY AND THERAPEUTICS, MEDICO-CHIRURGICAL COLLEGE.

It is a well-recognized fact that the course in practical pharmacy, as given in our medical schools, is greatly deficient in every way. If one carefully examines the curriculum of any medical school to-day, he will find an almost infinitesimal amount of time devoted to this subject, even in the best schools, and in some instances it is not taught at all; yet, almost without exception, a great amount of time is allotted to the major branches.

We all recognize the fact that each year the standards are being raised, both as to the preliminary requirements and also as pertains to the general course work, and rightly so; but is the amount of time devoted to practical pharmacy proportionately increased? Everyone must admit that it is not. But why not? Is a thorough knowledge of the drugs that we are to use in the treatment of disease of no value to the medical student? Is it of no value to the practitioner to know how to combine drugs so as to make desirable and palatable combinations, and preparations that are of a pleasing appearance?

Is it any wonder that homeopathy meets with the success that it does, when we note the nauseating, unsightly, and foul-smelling combinations that are often ordered by the physician? Every physician frequently meets people who give as their only reason for employing a homeopathic physician that their children take his medicine so much easier, and without resistance, and they themselves likewise prefer their medicine in a form easily administered. Everyone who has served behind the dispensing counter of a prescription store has compounded many horrible concoctions and remarked as he did so that "he is thankful that he is not the patient."

When a physician is called to see a patient it is necessary that he should first make a proper diagnosis of the disease with which his patient is suffering, and, in order that this can be done, the physician must possess a thorough knowledge of the fundamental subjects of medicine, viz., practice, surgery, gynecology, and the rest. This is a *conditio sine qua non* in order that he may intelligently treat that patient, but is it not equally essential that, in order that a cure may be effected, he should know what agents to employ, and how to administer them? Therefore, without a thorough knowledge of drugs (practical pharmacy) the physician cannot, and does not, cure his case; and, after all, is it not by our results that we are judged by the laity? There is no question but that a correct diagnosis and a proper treatment are equally important and essential to the successful practitioner. Now, if this be true, why is the one subject so thoroughly considered and the other almost entirely ignored in our medical curriculum? It can only be due to the fact that the medical profession does not recognize the true importance of a thorough knowledge of pharmacy, and this is especially applicable to those who represent the faculties of our medical schools. I was in conversation recently with a lecturer on pharmacy in one of our largest medical schools, and he told me that he has repeatedly petitioned the faculty of that institution for more hours to devote to his subject, and it has always been refused, on the ground that the time is already occupied, and no one desires to curtail his present course; some even had the audacity to tell him that he has already too many hours devoted to such an unimportant subject, and some of these very teachers write for the most disagreeable and incompatible combinations.

In an article by me in the *Journal of the American Medical Association* of January 7, 1905, entitled: "The Trend of Modern Prescription Writing," I showed, as the result of the careful examination of five hundred prescriptions from each of two of our leading pharmacies, that the trend of modern prescription writing was toward the use of proprietaries, as 35.9 per cent. contained them. Again, only 62.1 per cent. were written correctly, whereas this should have been near the hundred mark; and the great majority of these prescriptions were from the pens of our prominent teachers in our medical schools, the physicians, whom above all others should have a thorough knowledge of every branch of medical science. The criticisms in prescription writing applied to the endings used in designating the drugs or preparations, and the use of the proper official names as embodied in the inscription and the proper phraseology as applicable to the subscription.

A marked defect in the knowledge of prescription writing was especially noticeable among the recent graduates, and why? Several of these recent graduates who ranked as the "honor men" in their respective schools, and who likewise received the highest State Board averages, showed a most

noticeable deficiency in their prescriptions. Now, who is responsible for this deficiency? Is it the teacher, the defective means at his command, and insufficient time allotted for teaching the subject, or the student, that is at fault? The teacher is often a physician who has never received any practical pharmaceutical training other than the "smattering course" that he received as a medical student, and, as a rule, on account of limited training and lack of interest, he follows the same rut as his predecessor; as a consequence, the pharmaceutical laboratory is deficient in its equipment and very unattractive.

Because of these facts, officers and trustees consider this branch of medicine unimportant, and the student, not realizing the value of a pharmaceutical training, completes the course ignorant of its many valuable points; and usually not until he reaches the senior year, and commences to prescribe, does he fully realize his deficiency in the knowledge of the mode of preparation, appearance, administration, and effects of combining drugs, the very ammunition he is to use in firing his gun of knowledge, to combat disease. It is not, however, until as a physician, authorized to use blank and pencil and brought face to face with the patient, that he most seriously and keenly feels the sting of his pharmaceutic ignorance: he tries to formulate a palatable mixture, but fails; and, when he expects to find a nice, clear solution when he calls, he finds one with an unsightly and often dangerous precipitate. It is now after repeated failures that the horizon is filled with attractive-looking proprietary preparations, and these are substituted for the official drugs, because the label states that they are specific for the disease under consideration. As a result, this habit, once established, is continued through life, and this is the fault of the college, not the medical student.

One and three-tenths per cent. of the prescriptions examined contained dangerous combinations that would have resulted in serious consequences if administered as ordered. This shows two things: First, the importance of having our prescriptions compounded by competent pharmacists, who act as a "safety valve" when dangerous compounds are ordered, either through oversight or ignorance on the part of the prescriber. Second, the importance of every physician having a general knowledge at least of chemical combinations and how to combine drugs intelligently, in order to obtain the best results without forming dangerous compounds. A course in pharmacy in a reputable college is always a most valuable and useful foundation for the study of medicine when the student has the available time.

In order to determine how much time is devoted to pharmacy and materia medica in our medical schools to-day, and in order that I might convince myself as to the truthfulness of the reasons assigned for the above conditions, the latest catalogues of six of our leading medical schools, which are considered by everyone as the representative schools of this country, and whose standards are the highest, were examined with the results shown in the following table:

Course of Instruction	School No. 1	School No. 2	School No. 3	School No. 4	School No. 5	School No. 6
No. of hours devoted to lectures and recitations on Pharmacy and Materia Medica	15	72	45	60	72	48
No. of hours devoted to Pharmaceutical Laboratory instruction	16	24		60		16
No. of hours devoted to Prescription writing	Inc. in lect'res	15		Inc. in lect'res	Inc. in lect'res	15
No. of hours devoted to Prescription dispensing by the student	50					
Year of course in which instruction in Materia Medica and Pharmacy	Second year	Second year	Second year	First year	Second year	Second year
Year of course in which instruction is given in Pharmaceutical Laboratory	Second year	Second year	Second year	First year		Second year
Year of course in which instruction is given in Prescription writing	Second year	Third year		First year	Second year	Second & third year
Year of course in which instruction is given in Prescription dispensing	Third year					
Voluntary course in Pharmaceutical Laboratory. Optional. No examination			16			
Total hours devoted to Pharmacy, Materia Medica, and Prescription work	80	111	64	120	72	112

surprised that the average medical student is deficient in prescription writing? He could be nothing else. When we find that one of our leading medical schools would attempt to cover the subects of materia medica and pharmacy, and also prescription writing, in fifteen hours, and another not even mention it in the curriculum, what must we think of the regular class of schools?

The number of hours devoted to pharmaceutical laboratory work varies from none, in one school, up to sixty hours, with one school giving sixteen hours optional laboratory work. The subject is of so little importance that the student can exercise his own judgment in regard to it. The results can be readily anticipated. Only one school requires or even mentions practical prescription dispensing, and this school requires at least fifty hours. This is certainly a forward step, and one to be commended, as *no medical school can graduate competent men in the art of prescription writing without a thorough training in practical prescription dispensing, in which each student individually compounds various types of prescriptions.* Here lies the solution of the whole problem. Five schools give their instruction in pharmacy and materia medica in the second year, and one in the first year; this likewise applies to the laboratory work with the exception of one, which gives no laboratory work at all.

The course in prescription dispensing is best given in the third year, as the student is then better enabled to master the details pertaining to it.

The total hours devoted to the entire subject vary from 64 to 120, proving that some students receive double the instruction of others on these subjects.

As a result of the above investigation, the follow-

ing is recommended as the minimum requirements necessary to give a thorough course in practical pharmacy in our medical schools:

Ninety hours devoted to lectures and recitations on pharmacy and materia medica, with thirty hours laboratory instruction, in which representatives of all the official preparations should be made; this course is preferably given during the first or second year.

Thirty hours devoted to prescription writing, in which the student is thoroughly drilled in the formation and writing of prescriptions.

Thirty hours devoted to practical prescription dispensing, in which various types of prescriptions should be dispensed by the student. These two courses should be given during the third year, for reasons stated above.

Thirty hours should be devoted to a course in pharmacodynamics, in which the action of the most important drugs is demonstrated.

Total hours for entire subject, 210, in contrast to those of the above table. This, of course, should be supplemented by a thorough course in general and applied therapeutics during the third and fourth years.

If each medical college should adopt the above as a minimum standard on this important subject, then and only then would our medical graduates be able to write prescriptions correctly and for palatable preparations, properly combined. The treatment of disease would then be based on rational therapeutics, as it should be.

3708 Spring Garden Street

SOME POINTS ON THE DIAGNOSIS AND TREATMENT OF THE PRETUBERCULOUS STATE.*

By CHARLES F DISEN, M.D.,

MINNEAPOLIS, MINN.,

DEMONSTRATOR IN ANATOMY AND INSTRUCTOR IN OPERATIVE SURGERY MEDICAL DEPARTMENT OF HAMLINE UNIVERSITY.

As the term "pretuberculous state" *per se* is rather vague, I shall beg to premise that in this paper such a term refers to a particular condition of the system that predisposes a person to infection with the tubercle bacillus, or to the melting down of a preexisting tuberculous focus that in time had become latent. In our office practice we are consulted by a class of patients whose welfare seriously depends on an early recognition of the character of their trouble. The subjective symptoms may hardly amount to anything but a feeling of lassitude, loss of ambition, and indisposition to work. They are usually young people; may have no fever, no pulmonary signs, nor may we find tubercle bacilli present in their sputum, even if, on a most painstaking auscultation, we should elicit some subcrepitant râles. The pulse rate may be unduly increased by any little exertion. I have learned in my own practice to classify patients in two principal types of constitution, an acid and an alkaline one; and, as I am of the opinion that the alkaline type is very much less immune than the acid one to tuberculosis, it is my plan speedily to determine to which of the two classes a patient belongs. For such a purpose I apply two principal tests, one confirming the other. First, I determine the acidity of the urine passed some hours after a meal, by adding gradually a 1 per cent. solution of borax to 1 ounce of the urine, containing a piece of blue litmus paper. If much less than twenty minims are required to return a blue color to the litmus paper, I consider the urine subacid, and, excluding special known causes of a subacid—it may be neutral or even alkaline—urine, I suspect the patient with such a urine of belonging to the alkaline type. For the second test I resort to a microscopic examination of the blood. We shall need to gauge the basophile characters of the leucocytes, especially that of their nuclei; and, as this can be done only relatively, *i.e.*, by comparing the stained specimens with other ones taken from persons known to be robust, it is a prerequisite for our purpose that the technique be uniform.* After experimenting with a multitude of disappointing methods of fixing and staining, I have settled down on the following: Having taken smears in the ordinary way, heat them in a double-walled tin box. Not less than 12-15 minutes must be consumed to reach 290°F., and at 310°F. the gas is shut off. (My tin box is five inches high by five inches by six inches, and with a thermometer through the top, is placed six and a half inches above a circular gas stove.) Stain five minutes in 1 per cent. alcohol-soluble eosin in 70 per cent. alcohol; wash, and when dry stain one minute in 1-20 per cent. watery solution of methylene blue. The only test for the proper strength of the methylene blue solution is to see whether it stains the nuclei of the leucocytes of any person's blood alike. If the solution is sufficiently weak, we shall find different shades of blue with different patients. Anent the relations between the blood, the pretuberculous and the tuberculous state, Dr. Holmes of Denver† has presented some most valuable articles, to which the reader may be referred. Suffice it, however, for the present purpose to state that, if we find a low basophile character of the nuclei (hypochromatosis) and disintegration of spongioplasm, with a relative deficiency in number of the smallest lymphocytes, and possibly irregularity in the distribution of neutrophile granules, then a diagnosis of the alkaline type is confirmed, while the presence of a pretuberculous state should be suspected. We must base our opinion, however, not on the character of only one or two leucocytes, but on the predominating features as presented to us by a number of them. But let it be understood that an examination of the blood is never intended to postpone a diligent search for the tubercle bacillus. (Especially, because, when active tuberculosis has already supervened, and then the ominous polynuclear leucocytosis appears on the scene, it may happen that the nuclear staining qualities by way of defense of the organism become misleadingly normal. The softened contour provoked by the spongioplasmic disintegration of the leucocytes will, however, still be observed.) The disintegration of spongioplasm involving a softened contour of the leucocytes, it would not be unreasonable to conclude with Dr. Holmes that the same constituents of the more stationary tissues share a similar fate. Nor would it need a great stretch of our imagination, considering the lungs, to believe that a softened consistency and contour of the cells of the infundibula and alveoli may favor an ingress of the tubercle bacillus. Such a softened condition of the tissues, which also entails a diminished chemicovital resistance of the body, and frequently is accompanied with subacidity of the urine, I have allowed myself to couple with an increased alkalinity of the system. First, because the deficient basophile constituents, the chromatin and spongioplasm, are made up of

*Read before the Norwegian Medical Club.

*The experienced examiner will have established in his mind a normal standard for comparison, saving the work of taking smears from the healthy for that purpose.

†Medical Record, September 5, 1896; March 13, 1897.

nucleoalbumins; these are of acid reaction, and need phosphoric acid to be maintained. Secondly, because a subacid urine indicates deficiency of acid phosphate of sodium, and consequently a lack of some radical of phosphorus in the system; thirdly, because the nucleoalbumins—which were found in a state of disintegration—are soluble in alkaline fluids *pari passu* with the degree of alkalinity; and, lastly, because of my own clinical observations. Normal acid urine may, however, be met with in the pretuberculous state when the system contains too little calcium to bind the radicals of phosphorus, but such deficiency is compensated for by the presence of the still more alkaline cations, potassium and sodium. These elements, having a greater affinity than calcium for the phosphoric radical, and, as their (acid) phosphate combinations also are more diffusible than the corresponding calcium salts, it is only plausible that such circumstances would allow the phosphoric radical to be excreted in an amount that is out of proportion to what is actually retained in the system. Consequently, the alkaline type is then partly concealed and rendered manifest only by the low staining qualities of the nuclei, the softened protoplasm of the leucocytes, and, at least frequently, by soft and unduly translucent finger-nails.* Apparently, then, an examination of the urine might seem superfluous, yet it is necessary as having a bearing on the treatment. Now, then, if our patient, besides corresponding in the given manner to the blood test, and eventually to the urine test, tells of muscular debility, some loss of weight, increasing laxity of the tissues, and shows a thinning, softening, or high translucency of the nails, possibly also anemia, although the cheeks may be flushed, I should consider my suspicion of the pretuberculous state confirmed, especially if other tangible causes of deterioration can be eliminated. Increase of pulse rate, provoked even by a mere change of position, is ominous. Given a patient of the alkaline type, I should, in brief terms say that, while the alkalinity of his system heretofore may have been sufficiently low to allow a proper metabolism, now, when he is ailing, he may be in grave danger on account of an increased alkalinity. Katabolism, in consequence, is unduly increased, and creates a predisposition to tuberculosis, either by new infection or by the melting down of a preexisting focus. I believe that many a case of tuberculosis may be averted by recognizing the fundamental predisposing condition and instituting a rational method of treatment at an early date. We should especially be alert when we have before us patients between eighteen and twenty-five years of age, as they usually are the ones who present us with a pretuberculous picture, and cures of tuberculosis, developed at those ages, are exceptional. As for treatment, I should advise, besides an unrestricted amount of fresh air, phosphoric acid to maintain a normal acidity of the urine, also hypophosphite of calcium, almost raw, juicy beefsteak, and several raw eggs a day, with the view of promoting the anabolism of nucleoalbumins and fortifying the capsules of possibly preexisting tuberculous foci. Calcium salts are urgently indicated in the cases with acid urine to displace the more alkaline sodium element, as well as for the purpose of binding phosphorus to the system and preventing an excessive excretion of the latter substance. In the anemic cases we may add phosphate or hypophosphite of iron. The chief difficulty besetting our efforts would be the habitual tardiness of the public in seeking medical advice. But the fault lies partly with ourselves. The people, hearing so much of the rapid strides of medical science, expect from us anything short of miracles, and are led into procrastination with their troubles. They think that cure at any time depends only upon getting hold of the right man. It should be a part of our mission to inform the public that the practical outcome of medical achievements to date consists principally in prevention and early detection of disease at a time when cure may yet be possible, and that they must apply early if they shall expect to harvest from our progress. In fact, when disease has gained a strong foothold, we cannot, as a rule, with all our medical science nowadays, accomplish much more than was possible some thousand years ago. But this does not seem to be generally known, and the doctor is frequently unjustly blamed for his futile efforts, when really the late consultation by the patient and the shortcomings of science may be responsible for eventual failure.

[illegible] Century Building.

*Such cases with acid urine must not be confounded with what I previously have designated the "acid type," which is more susceptible to rheumatism than to tuberculosis.

EXAMINATION OF THE FECES OF TWENTY-FIVE STARCH-FED INFANTS, WITH A FEW CLINICAL OBSERVATIONS.

By JOSEPH H. LOPEZ, M.D.,

PHILADELPHIA

MEDICAL DIRECTOR OF CHARITY HOSPITAL; MEDICAL DIRECTOR OF ST. VINCENT'S HOME

Owing to the opinion in the minds of many practitioners that infants cannot digest starch, a chemical examination of the feces was deemed to be a more exact way of determining this than mere clinical observations. Knowing the quantity of starch given the infant and the percentage shown in the stools, an indication would be given as to the quantity digested and absorbed.

With this object in view, twenty-five infants of from two to six months of age were selected for the test, being put under close daily observation and the direct care of competent nurses, who prepared the babies' bottles strictly according to directions. They were fed as follows, five babies being in each class:

Class A, on wheat gruel: a day's feedings contained 1.5 per cent. of starch.

Class B, on arrow root gruel; a day's feedings contained 2.5 per cent. of starch.

Class C, on wheat and barley water; a day's feedings contained 2 per cent. of starch.

Class D, on home modified cow's milk.

Class E, on a highly saccharated food containing converted starch; a day's feedings contained 5 per cent. saccharated matter.

Infants fed on modified cow's milk (Class D) and the saccharated food (Class E) were so fed that results from these ways of feeding could be used for comparison.

Fifteen of the infants (some in each class) had perfectly normal digestion at the time of commencing the present work, while the other ten (some in each class) had suffered for some time from intestinal indigestion and had frequent bowel movements. The dejecta were collected daily for a period of ten days, in wide-mouthed bottles, and conveyed to the laboratory for examination.

It was found that the digestion of the infants of classes A, B, and C (both gastric and intestinal) was not impaired, and that those who suffered previously from intestinal disorders had less frequent bowel movements, increased in weight, and

were of better color and general appearance, indicating improved digestion and assimilation.

The amount of free starch found in the stools of the infants fed under the different classes was as follows:

Class A, .001 gram in 1 gm. feces.
" B, .051 " " " " "
" C, .027 " " " " "

It is interesting to note, by way of comparison, that the digestion of the infants was not impaired by the starch, while irregularities were frequently noted in those fed on home modified cow's milk (Class D), but this was corrected, and under a changed diet they continued to improve. This, however, cannot be said of those fed (also for comparison) on the saccharine diet, as in 50 per cent. of that class (E) gastric and intestinal disturbances were very frequent. The children in this class, after the test, were reduced in weight and appearance. They were eventually put on the same feeding as Class A, when they improved more rapidly.

The data on feces examination at hand were somewhat limited in detail, but the usual chemical methods, as follows, were adopted.

The feces were evaporated to dryness over a water bath. This was placed in a stoppered cylinder of at least 100 c.c capacity, and 50 c.c. of water and 3 c.c of sulphuric acid were added. The entire contents were boiled for three hours in order thoroughly to invert the starch. The water driven off by evaporation was replaced from time to time. After cooling it was filtered into a 100 c.c cylinder, washing the filter with water until 100 c.c. of filtrate were obtained. The glucose in this solution was determined by Fehling's solution, bearing in mind that 100 c.c. Fehling's solution represents .5 gram of pure anhydrous grape sugar, or .45 gram starch.

The experiments thus show that young infants can and do healthfully digest starch.

To Dr. Henry B. Ingle, pathologist to the Charity Hospital, we are indebted for his valuable aid in the above examinations.

SUPPURATING OMENTAL HERNIA: REPORT OF A CASE.*

By FORBES R. McCREERY, M.D.

NEW YORK

This case appears to me sufficiently unusual to merit reporting in detail. J. S., twenty-five years of age, single, born in Ireland, groom. About eight years ago, while at home in Ireland, patient was kicked by a horse in the right lower quadrant of the abdomen. At first he felt little pain, and was about to continue his work when he began to vomit. The abdominal wall became very "hard," but no lump or discoloration appeared. He remained at home one month, then was sent to a hospital. The vomiting and abdominal rigidity persisted, and it was thought that he would die. There was no pain. No operation was done, but his abdomen was blistered and he was bandaged. In about two months he recovered sufficiently to leave the hospital. He was soon able to work, but when he rode horseback he would occasionally have a "stitch in the side near the kidney." His previous health has otherwise been good, and there is no venereal or alcoholic history. Five or six months after the kick a lump appeared in the right inguinal region. This gradually worked lower until it entered the scrotum. At first it would go back when lying down. For five years it has not done so. He never wore a truss. During the late summer and fall of 1905 the patient's health failed so much that his friends feared he was developing either tuberculosis or typhoid fever. He had been exposed to typhoid. Late in November, 1905, I saw and examined him on several occasions. There was nothing to point to either of these diseases, but there was an irregular fever, sometimes absent for several days, again reaching 100° or 101°. No malarial organisms were found. On the right side a large, doughy mass extended from the internal ring to the testicle. Between the latter and the root of the penis was an accumulation of fluid, which I presumed to be pus, and thought to be distinct from the mass in the inguinal canal. The latter appeared slightly reducible, but did not fluctuate. No blood count was made. The kidneys and other organs were apparently normal. My diagnosis was irreducible omental hernia, with a scrotal abscess, distinct from the hernia, and of unknown origin, but possibly tuberculous. On December 2, 1905, with the assistance of Dr. Satterwhite, I operated. On exposing the mass it was found to be surrounded by old, dense cicatricial tissue. In attempting to isolate a sac an opening was made into a cavity containing grumous fluid. I closed the opening with a clamp, but soon made another. A number of small collections of pus were thus opened. The last one came from inside the abdomen, and was so deep that I could not reach the bottom with my finger. The entire mass of omentum seemed to be riddled with abscesses. The pus was odorless, and no tubercles were seen.

The omentum was tied off in sections, the stump secured just inside the internal ring, the sac sewn to the skin, and a cigarette drain passed to the bottom of the large intraabdominal abscess cavity. As much of the mass was then excised as was possible without risking injury to the cord. The scrotal wound was drained, and the intermediate portion of the wound sutured. I was anxious as to the fate of the testicle, as I feared that its blood supply might have been impaired. Recovery was satisfactory. Both wounds discharged profusely, and large masses of slough separated, especially from the scrotal wound. There was considerable induration around the stump of omentum, and I feared further trouble there. About January 1, after the patient had been up and out for a week or more, a residual abscess formed here, which finally opened into the old sinus. The scrotal wound healed about the third week of January. The abdominal sinus closed the first week of February. On February 16 both wounds are normal, the testicle apparently normal, and no sign of recurrence of the hernia. I expect that it will recur and a further operation be required.

The omentum was examined by Dr. George T. Biggs, who reports "interference with nutrition was chiefly responsible for the condition of the omentum in that hernia. There is demonstratable interference with blood supply owing to thickening of vessel walls. Also small foci of calcification in dead tissue. The abscesses are lined by granulation tissue. Cellular exudate is abundant, and there is much increase of fibrous tissue. Smears of the pus failed to show bacteria."

June 23, 1906.—About two weeks ago the patient returned for examination. A small hernia presented at internal ring. This I operated on on June 13. There was no sac, and on dissecting through the cicatrix, the general peritoneal cavity was opened, intestine and omentum presenting; the peritoneum was closed by purse-string suture and the usual operation done with apparent success. The ring admitted two fingers freely.

123 East Fortieth Street.

New York, September 29, 1906.

THE HUMANITIES AND MEDICINE.

THE present age is one it is the fashion to call eminently practical. Men are striving for "results," by which they mean success in their undertakings and the acquirement of wealth, and this in the shortest possible time. It is the age of the young man, and if "success" is not attained within the Oslerian limit of forty years the man is accounted a failure. The age limit is applied in every walk of life; the laborer, the clerk, the man who would enter the public services must all be young to have any chance of securing a lucrative appointment. The result of this is that the youth must scramble. He must fit himself for his life work in the briefest time possible, else he will be distanced by his competitors. His education can no longer be "solid"—it must be "practical." There is no time for the preliminary training of the mind to put it into shape for work along any lines, but in the acquisition of knowledge only those subjects are to be studied which are supposed to have a direct bearing on the future profession. The result is a race of specialists with the prizes to the "smartest" and the relegation of the man of average abilities to the drudgery of a clerkship with the nightmare of the age limit of efficiency always before him. Superficiality is the logical outcome of this tendency to the worship of youth, and one past the flush of youthful optimism must be possessed of an abiding faith in the common sense of mankind not to despair of the future.

The reaction, however, is bound to come, and, curiously enough, the artificial limitation of human activity established by Osler when he was himself within two years of the period of retirement, yet at the height of his mental activity, has given an impetus to it. Even the young man saw the folly of the assertion that nothing for the good of mankind had ever been accomplished by men over forty years of age and that activity in worldly affairs should cease at the age of sixty; the old man was spurred on by such a challenge to show what there was in him. The author of the assertion, himself, according to the age limit, a nearly worn-out machine, undertook at the age of fifty-eight to infuse new life into the medical school at Oxford, and if he belies himself, as all his friends hope he will, gives promise to accomplish this task before he really becomes useless to the world. In medicine, indeed, the young man has not yet arrived, or at least the old man has not yet departed. The majority of professors, consultants, and directors of laboratories are near or beyond the semi-centennial mark, but they are still furthering the progress of medicine. All the old men are not dead, and the time is coming when the wisdom of age will again receive recognition.

One of the signs of this reaction is apparent in the renewed discussion regarding the value of the humanities in the college curriculum. The opponents of Greek and Latin as obligatory subjects no longer have it all their own way, and the friends of classical learning are taking heart again, daring to assert that there is in the study of the so-called dead languages even something "practical" as well as of disciplinary value to the mind of the young. In the program of the Classical Conference, held at Ann Arbor, Mich., in March of the present year, there was a symposium on the value of the humanities as a preparation for the study of medicine and of engineering, in which the speakers were practically agreed that the professional man was poorly equipped for his life work without a grounding in these but recently despised studies. The medical side of the discussion was taken by Drs. Vaughan, Nancrede, and Hinsdale of the University of Michigan. The argument was that there is no royal road to learning, a trite saying, but, as Dr. Vaughan said, no less true than trite; and that the thinking apparatus of the young needs training in the same measure as the muscles and the gastric cells. As the latter cease to develop and even atrophy when the diet is solely of predigested food, so do the pyramidal cells of the brain fail of their highest development when supplied with like pabulum in high school and college. Exercise is essential, and there is no better exercise for the young brain than the study of the two great languages of antiquity. The close attention which the student must give to the variations in the structure of words, which to his delight he soon perceives indicate variations in the shades of meaning, trains his mind to habits of accuracy and precision which are in later life of inestimable service to him in experimental work and at the bedside. But apart from this essential training of the mind there is a practical side to the study of Latin and Greek, of the latter especially, in medicine which is worthy of attention. Greek is to this day, in its roots, the language of medicine, and no one who is not grounded in this, not dead but living, tongue can follow the progress of our science without infinite pains and a time-wasting thumbing of dictionaries. Four years ago Dr. Welsh of Baltimore delivered the fourth Huxley lecture in London, taking as his subject "Studies in Immunity." It was a most scholarly address, but necessarily, as the theme was new, bristling with strange scientific terms of Greek origin. His hearers were edified, but mystified, and the editor of an Edinburgh medical journal (published in "the modern Athens" of all places!) found it advisable to prepare an abstract, translated, so far as it could be, into the vernacular, so that his readers could grasp its meaning. Vaughan and Nancrede both referred to this handicap under which their students suffered in their ignorance of the language of medicine, saying that they could at once pick out those in the class before which they were lecturing who lacked a fundamental knowledge of Greek, by the blank expression with which they received any new technical term. The progressive medical schools in this country are constantly raising the standard, not only of technical studies, but of preliminary requirements,

and the day is not far distant, we may confidently hope, when a knowledge of Greek and Latin, and especially of Greek, will be required of all who seek admittance to a school of medicine. This will raise the age limit of entrance into medical practice, but it will increase the dignity of medicine as a profession and will make the individual who has entered upon his life work a year or two years later a better practitioner, and will also give him a foundation of solid learning which will add to his enjoyment of life. With reform in the methods of teaching, the extra time devoted to the study of Latin and Greek need not be excessive, and it will not be time wasted, for the linguistic training will make the subsequent acquisition of modern tongues, German and French, a light matter and a recreation in leisure hours.

FEMALE GENITAL ACTIVITY.

There has been much speculation as to what organ constitutes the basis of genital activity in the female and the usual manner of estimating the relative value of the different portions of the tract consisted in noting the effect produced on the patient by the removal of any one part. Thus the greater the mental and physical disturbance the greater the value of the part in question, and therefore the greater the importance of conservative treatment in disease of the same. It is a common belief that the ovaries exert the most important bearing on the physiology of the generative organs and a complete oöphorectomy before the menopause is consequently avoided as much as possible. W. Blair Bell (*Liverpool Medico-Chirurgical Journal,* July, 1906) thinks, however, that the evidence in favor of this theory is by no means conclusive, and that there are other factors which play an equally, if not more important part in the process. The uterus, he claims, must be credited with a higher function than merely affording a resting place for the reception and development of the impregnated ovum. The structure of this organ, he points out, is largely that of a secreting gland and to the (hypothetical) secretion to which it gives rise he applies the term "uterin."

It has been noted that patients in whom a vaginal hysterectomy has been done before the menopause without removal of the ovaries, go through a definite climacteric period, with all the usual symptoms. On the other hand, it is a matter of perhaps even more common observation that menstruation continues after complete oöphorectomy, which, for want of a better explanation, is attributed to an incomplete extirpation of the organs or "persistence of habit." Another clinical fact accepted by many observers is the continuance of menstruation after supravaginal hysterectomy, when a portion of the endometrium has been left behind. Neither do the ovaries atrophy in such cases, as they do when the uterus is entirely removed. All these facts are gathered together in support of the writer's theory that the internal secretion of the uterus is the important element in the sexual life of the woman, and that the menopause is due to atrophy of the uterus as a primary process with destruction of the secreting glands. That this is uninfluenced by the ovaries is shown by the fact that pregnancy has been noted after the menopause has been apparently fully established.

All this theorizing must, of course, be supported by clinical investigation, which is now being carried on by Dr. Bell. Uterine extract has also been administered clinically in a number of cases, but no definite conclusions have been obtained as to its action. The suggestions submitted by the writer of the article referred to are of considerable interest, and although there are several gaps still to be filled, his theory tends to explain many things in the physiology of genital activity which have thus far been insufficiently accounted for.

THE EFFECT OF TEMPERATURE CHANGES ON THE STOMACH.

Notwithstanding the extended attention which has been given to the subject, there is still a widespread difference of opinion between the physiologists and clinicians with regard to the matter of gastric sensation. Clinicians have long agreed upon a class of gastric disturbances which have been included under the general title of "neuroses." These seem to have little interest for the physiologist, however, and we find but slight attention given to the question whether the normal stomach can give rise to the sensation of either pressure or pain. As for the appreciation of heat or cold, this is absolutely denied to the stomach by the physiological investigator. This fact seems to be apparently confirmed by observations made during laparotomies which were carried out under local anesthesia, but, as Neumann points out in a recent article (*Wiener klinische Wochenschrift,* No. 30, 1906), no account was taken in these cases of the fact that the organ under trial was exposed to the air, and it has been shown conclusively that such exposure is accompanied by a well-marked anesthetic effect. In a further attempt to prove that the normal stomach could appreciate the differences between heat and cold, Neumann made use of a double tube, through which fluids of different temperatures were introduced into the stomach. It was found that the person on whom the experiment was tried could clearly appreciate the changes in the temperature of the fluid, and much more quickly, moreover, than if this was swallowed, because the influence of the esophagus could thus be eliminated. The same effect was obtained by the introduction of warm and cold water through a gastric fistula.

A knowledge of these conditions is of more than theoretical interest, for it will help us to recognize certain variations from the normal and to employ this knowledge perhaps in the differential diagnosis of certain gastric diseases. The most frequent deviation from the normal is to be found in hysteria, where there may be complete gastric anesthesia or a peculiar paradoxical condition in which cold gives rise to a feeling of heat, and *vice versa.* In another class of cases there is marked hyperesthesia and even slight degrees of heat or cold give rise to painful sensations. Neumann suggests that a practical application of this knowledge can be made in the treatment of such cases by regulating the temperature of the lavage water, and thus producing anesthesia of the mucosa. It may also be possible to employ this sign, gastric hyperesthesia, in the differential diagnosis of organic from functional diseases of the stomach, but that is matter for future observation.

A Pioneer Medical Man.

Probably the first, or at any rate one of the first members of the medical profession to land on the shores of this continent, was Dr. Diego Alvarez Chanca. This worthy, who held the position of physician in ordinary to the King and Queen of Castile and Aragon, came with Christopher Columbus on his second voyage of discovery in the year 1493. Dr. A. M. Fernandez de Ybarra, writing in *Janus* for August, gives an interesting account of this forgotten physician, with lengthy quotations from a letter which Dr. Chanca sent to the Municipal Council of his native city Seville, containing the first written description of the flora, the fauna, the ethnology, and the anthropology of America. Dr. Chanca is said to have saved the life of Christopher Columbus by his medical skill on more than one occasion, and on his return to Spain in 1506 published a treatise on the treatment of pleurisy. He was also the author of several other medical works. In the letter to the Municipal Council of Seville, Dr. Chanca writes concerning the West Indies: "The country is very remarkable and contains a vast number of large rivers and an extensive chain of mountains, with broad, open valleys, and the mountains are very high. It does not look as if the grass is ever out throughout the whole year. I do not think that they have any winter here, for at Christmas we found many bird nests, some containing the young birds and the others the eggs. No four-footed animal has ever been seen in this, nor in any of the other islands, except some dogs of various colors, as in our own country, but in shape and size like lapdogs. Of wild, ferocious beasts there were none. . . . . There is a vast number of trees, which yield surprisingly fine turpentine. Tar is found in abundance, of very good quality, too. We discovered trees which, in my opinion, bear nutmegs, but at present without fruit on them, and I say so because the bark tastes and smells like nutmegs. I saw one root of ginger which an Indian was carrying around his neck. There is aloes, too, though not of the same kind that we are acquainted with in Spain, but nevertheless a species of aloes that we doctors use. A sort of cinnamon has likewise been found, but, to speak truthfully, it is not of such a fine quality as the one we have in Spain; or, perhaps, this is so because now it is not the proper season to gather it, or the soil in which it was found growing in this vicinity is not well adapted." A fairly full description of the natives of the islands visited is given, with notes on climate. Altogether, the account is in a high degree instructive and goes to show that the Spaniards at the time Dr. Chanca wrote his narrative were the most civilized and cultured race of the world. Dr. Ybarra has done good service in unearthing the records of this once distinguished but now forgotten worthy.

The Nutritive Value of Fats Injected Subcutaneously.

In the Medical Record of August 25 we referred to this subject, pointing out that the experiments made by Winternitz with the object of testing the nutritive value of fat administered to animals subcutaneously showed that fats thus injected were of practically no therapeutic value. In the *American Journal of Physiology* for September, 1905, Drs. Yandell Henderson and Edward Francis Crofutt of the Physiological Laboratory of the Yale Medical School described a series of investigations made by them in regard to the subcutaneous injection of oil into animals. Dogs and cats were used for the purpose of experimentation by these investigators. The oil used was cottonseed oil, as by reason of its bright yellow color it is easily distinguishable from dog fat, it remains fluid at ordinary temperatures, it possesses a high iodine number, and it reacts characteristically and delicately to Halpen's test. After somewhat protracted and careful investigations Drs. Henderson and Crofutt reached the following conclusions: Oil injected hypodermically is readily and widely distributed through the subcutaneous spaces. Such oil is not, however, transformed *in situ* into adipose tissue. In fact, the tissues react to its presence as to any nonirritating foreign substance. In the blood, lymph, and milk it does not appear in detachable amounts. While the oil is ultimately absorbed and utilized in metabolism, the process is one of extreme slowness. Oil injections in any moderate amount are therefore practically without nutritive value. The conclusions of Winternitz were in accord with these, though he appears not to have known of the earlier experiments of the American observers; at least he ignores them in the article from which we quoted in a former issue. Subcutaneous feeding was employed in 1869 by Menzel, and King, Whittaker, and others have also employed this method, but without any definite demonstration that it was of value as a nutritive agent; von Leube, however, was of the opinion that injections of oil were of practical value in nourishing patients in such conditions as rendered it necessary, as in the failure of rectal enemata. Henderson and Crofutt think that von Leube misinterpreted the results of his experiments and accepted as true adipose tissue formed from the butter injected, what was really merely connective tissue impregnated with butter.

News of the Week.

Washington State Medical Association.—Dr. G. W. Libby of Spokane, president of the association, in his opening address at the annual convention recently held in Spokane, denounced the present methods of caring for the insane, which he declared to be crude, inadequate, and barbarous, and called upon his fellow practitioners to urge the members of the State Legislature to amend the Medical Practice Act so as properly to define the term "practising medicine." There was a large attendance of physicians, and two special guests were Hon. Albert E. Mead, Governor of Washington, and Mayor Floyd L. Daggett of Spokane, who both made brief addresses. Papers were read on the following subjects: Discussion on "Pleurisy," led by Dr. William Douglass of Tacoma; "Diagnosis and Prognosis of Pleuritic Effusions," by Dr. M. C. Robins of Spokane; "Clinical Course and Treatment," by Dr. J. Sutherland of Spokane; discussion, led by Dr. William Shannon of Seattle; "Angina Pectoris, Pseudoangina and Palpitation," by Dr. J. W. Bailey of Seattle; "Bradycardia, Tachycardia, Syndrome, and Arrhythmia," by Dr. William House of Portland, Ore.; discussion, led by Dr. H. W. Dewey of Tacoma; "Treatment of Organic Heart Lesions," Dr. H. W. Howard of Prosser, Wash.; "Osteomyelitis, Classification, Etiology, and Pathology," Dr. H. W. Reed of Seattle; "Clinical Course and Differential Diagnosis," Dr. W. N. Keller of Tacoma; "Treatment," Dr. A. A. Matthews of Spokane; discussion, led by Dr. E. M. Brown of

Tacoma; "Headache, Significance and Treatment," Dr. S. Sargentish of Tacoma. The following officers were elected for the coming year: *President,* Dr. J. H. Lyons of Seattle; *Vice-President,* Dr. E. L. Kimball of Spokane; *Second Vice-President,* Dr. E. E. Shaw of Tacoma; *Secretary,* Dr. C. H. Thompson of Seattle; *Treasurer,* Dr. G. H. Greer of Tacoma. The meetings will be held as follows: Seattle, 1907; Tacoma, 1908; Spokane, 1909.

Crusade Against Phthisis in the Chicago Public Schools.—As a result of the conference between members of the Chicago Board of Education and a committee from the Chicago Tuberculosis Institute, the following innovations are likely to be introduced into the school system: The establishment in every school building of a dispensary room for the examination of suspects and the treatment of cases; separation of the tuberculous pupils into two classes—contagious and non-contagious; the organization of a corps of visiting nurses, to visit the homes of suspects, dress open wounds, and report conditions to the board. It was pointed out that such a corps of nurses would render valuable service in reducing truancy by investigating all cases of illness and returning the sufferers from minor complaints to the school with all possible speed. Regular inspection of all schools at stated periods by medical inspectors; establishment of a system of surveillance for suspects and those suffering with the disease, with a view to excluding the victims the moment their presence in the classroom becomes a menace to the other children; the providing of special educational facilities for the victims of tuberculosis in its contagious forms; the segregation of all children suffering from tuberculosis of the bones.

Dedication of the New Harvard Medical School.—The new buildings of the Harvard Medical School, erected in the Fenway at a cost of $5,000,000, were dedicated on Tuesday of this week in the presence of a large number of physicians and other scientific men and men prominent in public life. The program consisted of prayer by the Rev. Dr. George A. Gordon, an address by Dr. John Collins Warren, Mosely Professor of Surgery at Harvard; presentation of the buildings by Charles Allerton Coolidge, representing the architects; a brief address of acceptance by President Eliot, and addresses by Dean W. L. Richardson of the Harvard Medical School, Dr. Thomas Dwight, Parkman Professor of Anatomy at Harvard; Dr. Frederick Cheever Shattuck, Jackson Professor of Clinical Medicine at Harvard, and the dedication of the buildings by President Eliot. On Wednesday there was an academic session at Sanders Theater, at which degrees were conferred upon a number of physicians and surgeons.

A Section on Pathology.—The proposal has been made in Ohio to organize a special section of the State Association for the study of pathology. One of the objects to be accomplished will be the establishing of a uniform technique in carrying out tests and other pathological work so that statistics gathered from different sections of the State may form a reliable basis for deductions.

Birth Rate in Paris.—The birth rate of this city continues to shrink, according to the latest report of the health authorities. There have been fewer births this year than last in every arrondissement except two, including one where the population is growing at the rate of 3,000 annually. One shows 400 fewer births than two years ago.

A Case of Suspected Typhus Fever.—The White Star liner *Cretic,* which arrived at Quarantine on September 18, was not allowed to dock until the following day, owing to the fact that a child had died during the voyage of what the ship's surgeon suspected might be typhus fever. The steerage passengers who had occupied the same compartment as the patient were removed to Hoffman Island for observation, and the ship was fumigated.

Civil Service Examinations.—The State Civil Service Commission will hold examinations on October 12, 1906, for the positions of assistant bacteriologist, $1,500, and assistant sanitary chemist, $720, in the State Department of Health; pupil nurse, Erie County Hospital; trained nurse, Westchester County Hospital. The last day for filing applications for these positions is October 8. Full information and application forms for any of these examinations may be obtained by addressing Mr. Charles S. Fowler, the Chief Examiner of the commission, at Albany.

Catheter Scales.—The American Surgical Trade Association announces that at a meeting held in Philadelphia, June, 1906, it was resolved that in order to secure uniformity, after January 1, 1907, the trade adopt the French scale for all catheters, bougies and sounds. Physicians are requested after that date to use only the French scale in ordering such articles.

Illness of the Pope's Physician.—Dr. Lapponi, physician to the Pope, is reported to be seriously ill, and it is stated that Dr. Mazzoni has made the diagnosis of inoperable cancer of the stomach.

Unveiling of the Semmelweis Monument.—On September 30 the monument bearing the statue of I. P. Semmelweis, which has been erected in Budapest as the result of subscriptions from all the civilized countries, is to be unveiled. The movement to commemorate the work of this benefactor of womankind was begun in 1891, when the medical faculty of the University of Budapest caused his body to be brought back to his native soil and to be reburied in state. A suitable monument was erected over the grave and a memorial tablet was placed on the house in which Semmelweis was born. The present statue has been placed in the most beautiful public park of the city, the Elizabethplatz.

Memorial of Major Walter Reed, U. S. A.—The executive committee having charge of the collection of the sum of $25,000, the income of which is to be paid to the widow of the late Major Walter Reed, U. S. A., and the principal to be reserved for a permanent memorial in the city of Washington in commemoration of his services to mankind in investigating the transmission of yellow fever, announces that the amount now subscribed is somewhat over $16,000. To complete the fund and cover incidental expenses, including a marble bust of Major Reed, $10,000 is needed. The desire of the committee is to close the subscription before the end of this month. Communications should be addressed to the secretary, Gen. Calvin De Witt, U. S. A., No. 1707 Twenty-first street N. W., Washington, D. C.

Health of the City of Chicago.—To the unseasonably high temperature and humidity is attributed a slight increase in the city's mortality. This increase occurred largely in the cases of persons over sixty years old, the victims of chronic diseases. There were fewer deaths under five years of age than in other compared weeks. There is a serious increase of typhoid fever in the city, due, it is be-

lieved, to milk contaminated with the poison by the use of polluted water in washing cans and other utensils. The department has closed one infected milk depot and excluded milk from two dairies pending the bacteriological examination of their water supplies. Upward of sixty cases of the disease have been located and the premises are being inspected with a view to the correction of any sanitary defects found to exist, as well as to proper isolation of the cases, disinfection, and other measures of restriction.

Meat Condemned.—The Health Department inspectors at the Union Stock Yards, Chicago, condemned and destroyed last week 95,608 pounds of meats, 11,545 pounds of which had been passed by other inspectors. The fish inspector condemned 25,950 pounds of fish and about 14,000 pounds of other food stuffs.

The Dallas (Tex.) College of Physicians and Surgeons will on October 21 begin its first term in the new building recently completed for the institution.

India's Death Rate from Wild Beasts.—Statistics published in India show that in 1904 there were killed in that country by snakes and wild beasts 24,034 persons—21,880 by snake bites, 796 by tigers, 399 by leopards, and the rest by other animals. The number of cattle killed was 98,582. The other side of the account shows that 65,146 snakes and 16,121 wild animals were killed, for which rewards of £7,313 were paid.

American Hospital in Constantinople Burned.—The new American Hospital and Training School for Nurses recently established in Constantinople by Dr. Thomas S. Carrington of this city, was burned to the ground on the eve of its formal opening, at a loss of $10,000, partly covered by insurance. The Board of Directors proposes to rebuild at once, and plans for raising the funds are under way.

St. Gregory's Hospital Under New Management.—The financial management of this institution has been taken over by the Volunteers of America. Ballington Booth, who is commander of the organization, states that it will have equal voice with St. Gregory's Society, consisting of fifty directors, and that all the requirements of the State Board of Charities have now been complied with, so that the managers of the hospital expect to have a charter granted when they make application for it next month.

Medical Society of Virginia.—The thirty-seventh annual meeting of this society will be held in the hall of the University of Virginia, Charlottesville, October 9 to 12, 1906. The president of the society is Dr. Lomax Gwathmey of Norfolk, and the corresponding secretary is Dr. John F. Winn of Richmond.

Berkshire, Mass., Medical Society.—The annual outing of this society was held at the Russell villa, on the south shore of Pontoosuc Lake, on August 30, under the presidency of Dr. Alfreda B. Withington of Pittsfield. About forty members were in attendance. Dr. George W. Gray of Boston read a paper on gallstones and their treatment.

New Medical Society.—A district medical society was organized at Albany, Mo., on September 11 by the physicians of Harrison, Gentry, Worth, and De Kalb counties. The following officers were elected: *President,* Dr. A. H. Vandivert of Bethany; *Vice-Presidents,* Drs. Gwynn of Clarksdale, Whitely of Albany, and M. H. Eads of New Hampton; *Secretary,* Dr. A. C. Long of Denver; *Treasurer,* Dr. J. W. Conard of Albany.

American Institute of Homeopathy.—At the recent meeting of this organization, held at Atlantic City, officers were elected as follows: *President,* Dr. E. D. Hooker of Hartford, Conn.; *Secretary,* Dr. Frank Kraft of Cleveland; *Treasurer,* Dr. T. Franklin Smith of New York.

Oakland County (Mich.) Medical Society.—The following were elected as officers at the annual meeting of this society, held in Pontiac on September 12: *President,* Dr. Moore; *Vice-President,* Dr. McKinnon; *Secretary and Treasurer,* Dr. C. D. Morris.

Washington Association for the Prevention and Relief of Tuberculosis.—The following have been elected officers of this association: *President,* Dr. C. H. Smith of Seattle; *Vice-President,* Dr. E. E. Heg of Seattle; *Second Vice-President,* Dr. Wilson Johnston of Colfax, Wash.; *Secretary,* Dr. W. R. M. Kellogg of Spokane; *Treasurer,* G. S. Brooke.

Obituary Notes.—Dr. George F. Lightfoot of Arlington, N. J., died on September 18, in St. Michael's Hospital, Newark, at the age of forty-one years. He was a graduate of the New York Homeopathic Medical College in the class of 1891 and had practised in Arlington for many years.

Dr. E. A. Wheeler of Brooklyn died suddenly on September 18, at the age of fifty-six years. He was born in Moodus, Conn., and received his medical degree from Bellevue Hospital Medical College.

Dr. S. G. C. Pinckney of Atlanta, Ga., died at Grand View, N. Y., on September 20. Dr. Pinckney was born at Grand View in 1869 and was graduated from the New York College of Physicians and Surgeons in 1893. After practising for two years in New York City he moved to Atlanta, Ga., where he made a specialty of nervous diseases.

Dr. Walter E. Fisher of New York City died from apoplexy on September 18 while hunting in the Austerlitz woods near Chatham, N. Y. Dr. Fisher was forty-five years old and had interested himself especially in nervous diseases.

Dr. C. A. Ruggles of Stockton, Cal., died on September 11, at the age of seventy-seven years. He was a member of the State Board of Health for fifteen years and served for four years as its president. While vice-president of the National Conference of State Boards of Health he was selected to make a special report on leprosy, to do which he visited Molokai. He had practised in Stockton for thirty-seven years.

Dr. William Oates of Bridgeport, O., died at the North Wheeling, W. Va., Hospital on September 19, of typhoid fever. He was born in Windsor Locks, Conn., and was thirty-four years of age.

Dr. J. D. Seymour of Whately, Mass., died on September 10, at Brattleboro, Vt., of apoplexy. Dr. Seymour was born in Greenfield fifty-six years ago and received his medical education at Harvard Medical School. He had practised in Whately since 1878.

Dr. Sherman T. Brown of Denver, Col., died on September 15, of appendicitis, at the age of thirty-eight years. Dr. Brown was operating when the first symptoms of his illness appeared, and he finished his work only at the cost of much personal suffering. He was operated on the same night, but died several days later of pneumonia. He received his medical degree from the Gross Medical School in 1894 and had practised in Denver since that time.

Dr. William K. Otis of this city died on September 22, of pneumonia. He was a son of the late Dr. Fessenden Otis and was well known as a genito-urinary surgeon. He was graduated from the College of Physicians and Surgeons in 1885 and had held many clinical and teaching positions.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LUNACY COMMISSIONERS' REPORT, INCREASE CAUSES, ETC.—A HEAT WAVE, EFFECT ON HEALTH—LONDON TRAFFIC, REPORT ON NOISES, VIBRATION, ETC.—DONATIONS TO HOSPITALS—HUXLEY LECTURE—WORKMEN'S SANATORIUM.

LONDON, September 7, 1906.

THE sixtieth annual report of the Commissioners in Lunacy was issued yesterday, and contains, as usual, a mass of statistics bearing on the management of asylums and the prevalence of the disease. The figures offer a feeble gleam of satisfaction from the fact that the increase in lunacy last year was less than in recent periods, although still considerable. The number of certified lunatics on January 1 was 121,979, which is 2,150 above the number on the same day in 1905, 2,630 in 1904, 3,235 in 1903, 3,251 in 1902. The annual average increase for the ten years ending December 31, 1905, was 2,554; for the five years to the same date, 2,807. Thus, last year's increase was less by 404 than the annual average of the decenium, and 657 less than that of the quinquenium. Turning back to 1859, we find the certified insane then numbered 36,762, and these figures have risen to 121,979 now, or rate of increase equal to 231.8 per cent. During that interval the general population has increased at the rate of 75.4 per cent. The increase of lunatics has been going on year by year, but not in equal proportions. The number on the first day of the year stood to the estimated population in the proportion of 1 to 283, or 35.31 per 10,000—an increase of 0.62 on the ratio for last year, contrasting with an actual numerical growth of 1.79 per cent. In 1897 this ratio was 31.89, so that in the decade it increased 10.72 per cent., the proportion of insane rising from 1 in 314 to 1 in 282. The actual increase of population in this period is recorded as 10.8 per cent. A table of the assigned causes of insanity in all the cases during the five years, 1900 to 1904, shows how great is the predominance of intemperance, being 22.5 per cent. of the males and 9.2 per cent. of the females. Other assigned causes are domestic trouble, pecuniary difficulties, overwork and worry, religious excitement, love affairs, fright and shock; but none of these approach the percentage due to drink, the figures varying between 0.5 and 8 per cent. Hereditary influence was ascertained in 19.2 per cent. of male and 25 per cent. of female cases.

How far an attack of insanity is related to the occupation of the patient is a subject the Commissioners consider deserving careful attention, but the material at their disposal permits an approach only to the fringe of the question. They offer as a contribution an examination of the returns of four asylums receiving patients mainly from agricultural communities. Comparing them with the general returns, they say in these districts the causes above the mean were religious excitement, sexual excess, sunstroke, old age, privation, heredity, and congenital defects; causes below the mean were domestic trouble, adverse circumstances, mental anxiety, shock, fright, and intemperance. This result they consider bears out what might have been assumed as to rural communities, but I think many will be disposed to disallow the assumption, at any rate, as to some of the causes.

Some account is given of extension of accommodation going on, and more required, and a regret expressed that the deficiency mentioned in the previous report has not yet been made up.

Finally, the Commissioners regret that no addition has been made to their number to enable them to cope with their ever-increasing duties.

We have had our little "heat wave," and some invalids have suffered rather severely. I qualify it as little, for we do not get such great heats as you experience in New York, nor do they last so long. Still, a sudden rise of the thermometer to 90 after a prolonged stay in the 70's is apt to produce collapse in the weak, and even the robust feel it severely when they persist, as so many do, in their usual habits as to food and drink, and refuse to adapt their clothing to the changed conditions. There have, as a matter of fact, been numerous cases of "heat-stroke" and a few fatalities—one of suicide, if not more. On Tuesday evening a welcome rain set in and brought cool breezes. In London above one inch fell during the night, and so we seem to have wound up one of the finest and most delightful summers for many years past; and, on the whole, the public health has been good. Summer diarrhea has, of course, been talked about in places, but I think it has been less prevalent generally than usual.

The report of the Select Committee on Cabs and Motor-Omnibuses was issued on Wednesday. The Committee take a broad view as to the vibrations, the noise and other forms of nuisance caused by the new motors. A person taking a house on a main line of metropolitan traffic must be prepared for the noise, etc. But one who, for health or other reasons, takes a house outside, has just reason to complain when the main traffic is diverted to pass his door for the profit of a private enterprise. Heavy, slow-moving traffic crossing London should be restricted to certain routes and certain hours, and not permitted to take short cuts through residential districts or narrow thoroughfares. These views will be heartily indorsed by many who have suffered from the noise and vibration of traction engines passing through streets at all hours of the night and destroying the hope of sleep for many an invalid or weary worker. The Committee say improvements might be enforced which would reduce the noise of the machinery itself to a low hum, and other improvements would lessen vibration. They recommend licensing of vehicles and of routes and stopping places; also, they would increase the powers of the police to regulate the traffic, though the powers possessed have not so far been fully employed.

Lord Iveagh has given £1,000, and Mr. H. T. Phillips £200 to the ophthalmic department of the London Hospital. A second anonymous sum of £1,000 has been sent to St. Mary's Hospital towards the Clarence Memorial wing.

Professor Pawloff of St. Petersburg has agreed to give the sixth biennial Huxley lecture at Charing Cross Hospital on October 1. His subject will be "Recent Advances in Science and Their Bearing on Medicine and Surgery."

Considerable progress is being made with the building of the sanatorium for tuberculous workers. The project, of which I have sent you some particulars, is to treat workers at the early stage. The post-office employees undertake to maintain 25 beds, the Hospital Sunday Fund 5, the Club and Institute Union 2, the Royal Oak Society 7, the Foresters, the Railway Servants' Society, each 1, and the Teachers' Union, 2. Thus, the building once completed, will, it is calculated, be self-supporting. But to secure this result rigid economy will have to be practised, and the out-door work of the patients will contribute somewhat to the table, the kitchen garden affording agreeable employment for some. Some novelties will be tried in the building. No brickwork is to be used, but tiles and steel supports employed, it is believed, will be found effective. The interior is, of course, designed to give, as far as possible, no lodgment to dust.

OUR LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

SYPHILIS AND VENEREAL DISEASES IN THE PROVINCES—FREE CIRCUMCISION—TURKISH COFFEE—THE PLAGUE AT TREBIZOND.

CONSTANTINOPLE, August 31, 1906.

IN the central districts of the vilayet (province) of Sivas syphilis and other venereal diseases are raging in rather alarming proportions. This is due principally to the great ignorance of the rural population, who take recourse to all sorts of doubtful domestic remedies, and almost never call for medical assistance. Whole families are in this way infected, and the loathsome maladies are propagated with ever-increasing intensity. The lack of medical men is also sadly felt in certain places, thus increasing the danger to which the public health is being exposed. The sanitary inspector of the province has therefore asked the central authorities in the Turkish metropolis quickly to adopt all the necessary measures, in order to check the spread of the contagion and to treat effectively the infected cases. The Ottoman Government has already taken the required precautions and measures with regard to these maladies reigning in other vilayets, and it is proposed to do the same for Sivas. Special hospitals will be constructed, of sufficiently large dimensions to admit and isolate as many sufferers as possible. It is intended to give the latter gratuitous treatment. It is also intended to appoint two medical specialists at a reasonable salary, whose duty it will be to visit the contaminated localities and give treatment to all seeking medical assistance. A sum will be granted them to cover the expenses of traveling about, as well as the expenses of drugs and instruments. It has been also decided to construct a hospital at Sivas itself, with fifty beds. The authorities of the vilayet will have themselves to find the necessary funds.

On September 1 the Padishah Abdul Hamid celebrates the thirtieth anniversary of his accession to the throne of the Ottoman Sultans. One of the most curious religious ceremonies that takes place on that day is the gratuitous circumcision of Moslem children and youths at the expense of the Padishah's private purse. The age prescribed by the Koran for circumcision is the completion of the thirteenth year. This, however, varies considerably, according

to circumstances. Frequently youths of twenty years of age, and even above, present themselves for this religious operation. The Sultan's Hamidié Hospital is then overfilled with fathers and their offspring, who patiently wait for their turn. The little surgical performance goes on day after day for a whole week and more. Thousands of children are being circumcised daily. The operation done, every one receives a basket of sweetmeats in the name of the Sultan, and also other presents of different kinds. A number of wards and pavilions of the above-mentioned hospital have already been arranged and equipped for the purpose.

It is generally believed that Turkey is very rich in coffee and exports the latter in much larger quantities than it receives it from other countries. Now, this is not the case. The annual export amounts to 4,853,423 kilograms, whereas the import of that product, so much valued in the Orient, is about double the amount, *i.e.* 9,350,458 kilograms. Brazil is the principal country whence coffee is imported in large quantities. Real good Moka of Yemen is at present comparatively rare. This is due to a disease of the grain which has begun to manifest itself of late in alarming proportions. In consequence of this disease, which has not yet been properly investigated, the interior of the coffee grains becomes foul and soft, and the exterior black. A short time ago several coffee branches with diseased grains were sent to Constantinople for purposes of analysis and investigation. The Ministry of Agriculture is going to make the necessary examination, and intends doing all in its power to prevent further destruction of the valuable Yemen coffee. In Turkey itself coffee is very frequently mixed with other ingredients, sometimes harmless, sometimes deleterious to health. Of the ingredients which are rather of a useful nature, one is the powder of dried figs. This admixture is also in great vogue in Austria, in some parts of Germany, in Roumania, and in Servia. The powder is added to coffee in the proportion of one to three. The beverage so prepared is of a deeper color, loses much of the exciting properties of pure coffee, and possesses even considerable nutritive value. In this country, indeed, people often use simple fig powder as a drink.

Several cases of plague have occurred in Trebizond, on the Black Sea. The last news from that place is that this week no fatal cases have manifested themselves. The superior sanitary council of Constantinople has, therefore, somewhat altered its previous injunctions of a very strict nature. Steamers will be now allowed to land at, and to leave, Trebizond harbor, but only for the purpose of receiving and disembarking cargo. No passengers will be allowed to leave the place and none to land. Sailors will be strictly forbidden to quit their vessels.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 13, 1906

Artificial Nauheim Baths in Chronic Heart Disease.—P. K. Brown states that the cases particularly fitted for Nauheim treatment are those in which the heart muscle acts insufficiently either from dilatation, poor blood supply due to anemia, or arteriosclerosis with changes in the muscle, acute or chronic, tobacco poisoning, and moderate fatty changes. Twelve clinical histories are given. Concerning the use of resisted movements in connection with the baths, the author states that he does not consider them essential, and they are not in his view as lasting in their effects as is the bath. They are often very tiresome to the patient, and are in bad cases actually dangerous unless given by someone who fully understands their purpose and makes a careful study of each individual case. Brown prefers to give them an hour or two before the bath; but if this is not possible, it is better to wait some hours after the bath. As regards massage in connection with treatment, he has found it of advantage when the temperature of the water was below 90° in securing a prompt reaction from the sensation of cold which patients with sensitive skins frequently have as the result of cutaneous stimulation. It is necessary that the patient be placed in a warm room and have his extremities well rubbed if there be much discomfort from the sensation of cold. The author describes in full his experience in the preparation of the artificial Nauheim salts. In his judgment the use of these salts at home under careful supervision of the physician gives just as good results as at Nauheim, and the régime is far more convenient and agreeable to the patient.

Systemic Infection Through the Tonsils.—J. L. Goodale notes that there occurs at the tonsillar surfaces emigration of phagocytic leucocytes, penetration of inorganic, or at least non-living matter, and the arrest of the lacunar bacteria at the lining mucous membrane. It seems probable, also, that the buccal secretions compose largely the fluid carried from the tonsils to the adjacent lymph glands. Obviously bacterial products may be taken up in the same manner. All that is necessary is that a given toxin shall come in contact with the epithelium of a lacuna. The result depends on the intensity and character of the toxin and the duration of contact. The toxemia is therefore acute or chronic. As an example of the former we have the ordinary acute tonsillitis. If this subsides, leaving the inflammatory plugs in the lacunæ, we may have them undergo degeneration and retention. Such conditions are often overlooked, because the tonsil is not thoroughly explored. These changes with consequent absorption of the products of decomposition may occur even in the small atrophied tonsils. Ultimately it is possible to produce in this way systemic infection eventuating in either tuberculosis or infectious arthritis. It is not necessary to assume that the organism of this disease entering through the tonsil should cause local reaction in this organ. It would seem probable that a condition of faulty drainage from the crypts would afford a given infectious organism better opportunity to remain in contact with the lacunar epithelium, possibly multiplying upon the detritus there found, and upon a favorable opportunity of becoming drawn into the tonsillar tissue with the current of buccal fluid.

New York Medical Journal, September 15, 1906

Ocular Inefficiency and Some of Its Results.—E. M. Alger comments on the difference of opinion on the "eyestrain" question and the conflicting clincal reports which appear from time to time. This is due partly to lack of definition in terms. The problem of eyestrain is an individual muscular problem and the determination of the exact point where the physiological merges into the pathological depends not only on a proper estimate of ocular defects and individual capacity for compensation, but also on careful consideration of a number of variable factors, such as age, general health, and the conditions under which the eyes are constantly used. Aside from the fatigue arising from the constant use of overtasked muscles, there are several phenomena which seem to be the central results of strain. Then in addition there is a steady mental strain due to failing ocular compensation. Ocular headaches may be either accommodative or muscular. As a rule an ocular cause may be suspected in headaches which occur regularly and get worse in the afternoon, are increased by close work, and are relieved by rest and holidays. Chorea is another malady in which a dependence on ocular insufficiency has been suspected and an examination of the eyes is always advisable in persistent cases. So also in neurasthenia we may frequently find the exciting factor to be the overuse of eyes whose compensation is strained. That this factor exists in many cases of migraine is generally admitted. In such cases optical errors are often family traits, and they cause not only accommodative and muscular asthenopia but a mental exhaustion as well, from the constant necessity of interpreting disordered retinal images

The Diseased Tonsil as a Causal Factor in Respiratory and Gastric Disease.—A. R. Solenberger firmly believes that diseased conditions of the tonsil in adult life are the cause of many respiratory and gastric disturbances. These conditions are often overlooked, but if one will thoroughly explore the tonsil and surrounding parts one will find that it is bound down by adhesions, the caliber of the crypts is distorted, and material is imprisoned in their deeper recesses which undergoes decomposition and furnishes pabulum for bacterial growth whereby the resistance power of the system is lessened. The insertion of a probe into the deeper pockets of such tonsils is often followed by the escape of pus or grumous fluid which is extremely offensive. Tonsillar symptoms are not always in evidence in such cases except that such organs are always subject to periodical attacks of inflammation, each one of which leaves the organ still more crippled and more potential for harm. Not alone on the respiratory and digestive tracts are these deleterious effects exerted. The middle ear is often affected through the Eustachian tubes. In the air and food tubes nature endeavors to interpose a barrier to the absorption of bacterial products by a change in the character of the epithelium lining the respective channels, but this barrier is often surmounted. The latter portion of the paper is taken up with the question of the removal of such offending tonsils as those described. Every vestige of diseased tissue should be eradicated.

The Kidney of Pregnancy.—D. W. Prentiss refers to the recent voluminous literature on this subject and divides the cases into the following classes: (1) Physiological kidney of pregnancy or mild passive congestion; (2) severe passive congestion with cloudy swelling, and (3) advanced parenchymatous nephritis. The results of our analysis in each of these groups are summarized, together with their respective symptoms. During pregnancy regular examination of the urine and estimation of blood pressure should be made. Patients should be instructed to report at once the occurrence of continued headaches, edema, or diminution in the amount of urine secreted. The author reports one case, deemed by him as one of passive congestion followed by cloudy swelling and progressing to a marked granular degeneration of the epithelium. Artificial delivery at the eighth month was effected, both mother and child surviving.

Journal of the American Medical Association, September 15 and 22, 1906.

Treatment of Progressive Atrophy of the Optic Nerve Due to Acquired Syphilis.—Charles Stedman Bull discusses the treatment of syphilitic atrophy of the optic nerve by means of subconjunctival injections of corrosive sublimate, the paper being based upon the writer's experience in twenty-five cases occurring in private practice. In three of the cases, in addition to the subconjunctival injections, an intravaginal injection was made directly into the sheath of the optic nerve. The results of this treatment were most discouraging; in none of the cases was there any permanent, and in only three was there even a temporary improvement. The most that could be said was that the injections caused no acceleration of the loss of sight. The following are the author's conclusions: (1) Posterior subconjunctival injections of sublimate may be given with but little pain if the sublimate injection is preceded by the injection of cocaine. (2) The conjunctiva should be incised and carefully separated from the episcleral tissue, and the injection made far back toward the apex of the orbit. (3) The eye need not be bandaged after the injection, but cold applications should be made for half an hour. (4) This method of treatment of cases of atrophy of the optic nerve has, in my hands, proved of no more value than the usual routine, treatment by mercury, potassium iodide, strychnine, and offers no encouragement for its continued use.

Neoplasms of the Colon.—A. F. Jonas reports sixteen cases of new growths of the colon and presents a study of the condition, based upon these cases. There is no disease of the intestine so free from symptoms in its early stages, and herein lies the great danger; for by the time the condition declares itself by unmistakable symptoms it is usually too far advanced for successful operative treatment. These may be colicky pains, flatulence, obstinate constipation, alternating perhaps with diarrhea, possibly emaciation, but the only positive sign is the presence of a tumor, which examination shows to be located in the wall of the colon. In the author's cases the new growth was malignant in all but one. The results of treatment are discouraging, for recurrence is the rule. By the time the clinical symptoms are sufficiently pronounced to warrant an operation the metastatic deposits will have become so extensive that one cannot hope to eradicate all of them.

Medical Treatment of Duodenal and Gastric Ulcer.—A. Lambert says the conditions to be overcome in the treatment of this condition are hyperacidity and sometimes hypersecretion and stasis of food in the stomach; nausea, vomiting, and pain arising from the morbid processes present in the gastric mucous membrane; the general conditions and symptoms of nervousness and anemia arising from the faulty nutrition of the body; and not infrequently the complications of hemorrhage, perforation, and at times stenosis and distortion of the pylorus or other regions of the stomach. The first essential in the dietetic treatment is complete rest of the body and the stomach, obtained by confinement to bed and rectal feeding. The latter should be continued for from three or four days to a week or ten days, but gastric feeding should be resumed before the rectum becomes intolerant. The first food swallowed should be peptonized milk in small doses and at long intervals, a quart a day being the limit reached at the end of a week, this being gradually increased until two quarts are taken in the twenty-four hours. The degree of peptonization may now be gradually reduced until, at the end of the third week, raw milk may be given. As we reduce the peptonization we may add the cooked cereal gruels of barley, wheat, or oat flour as part of the diluent. During the fourth week, with the raw milk, we may add crust free bread, butter, and eggs, but not hard boiled. It is well to add only one new thing at a meal, that we may judge accurately if it agrees with the patient, and be ready to discontinue it if necessary. In the fifth week one may add potatoes (baked or boiled), rice (boiled), macaroni, custards, chicken, and sweetbreads. In the final or sixth week of the cure, beef, mutton, green vegetables, light salad without vinegar, cooked fruits, and simple puddings may be added.

Sigmoid Pathology.—H. D. Niles thinks that angulations and partial obstructions of the colon at this point are more common than has been generally believed, and shows how pressure from hardened feces under such conditions may easily be the cause of ulcer and later of malignant disease. Incomplete nonmalignant stricture occurs probably next in frequency to ulcer in this region. The early recognition of sigmoid ulcer and its complications is, therefore, of the utmost importance, and especially since the after-results may be so serious. A suggestive history, left-sided tenderness, with or without bowel inflation, colicky pains, pus or blood in the stools, obstinate constipation, or obstructive symptoms, other diseases being excluded, are signs that should suggest a sigmoid pathology. Inspection, palpation, and percussion, before, during, and after distention of the bowel with water or air, are specially mentioned as valuable for detecting and locating stenosis in this part. The essential treatment, as in gastric ulcer, is rest, and timely operative measures, irrigation and starvation methods failing, are indicated.

Nephrolithiasis.—A. H. Cordier says that nephrolithiasis is more prevalent than is generally supposed, and that there seems to be some special cause for its more frequent occurrence in the right kidney. A stone once formed in the pelvis of the kidney, if too large to pass out, will sooner or later cause trouble. Suppuration, as a rule, is a late process, and should be anticipated by early operation. With a carefully obtained clinical history, diagnosis is easy. Obscure persistent pains in the kidney region, with the history of previous renal colic, should lead to an exploration of the organ. The patency of the ureter should be assured at the time of operation, and this existing, the kidney should not be removed unless it is practically destroyed by the disease. Medical treatment may be palliative to tide over an attack, and possibly may prevent a recurrence. He advises care as regards the use of morphine, lest a cumulative effect of too frequently repeated doses be caused when the tolerance due to the pain has ceased with the cessation of the attack.

The Present Status of Brain Surgery.—M. A. Starr considers that sufficient time has elapesd to enable us to estimate the value of brain surgery for the relief of tumors, epilepsy, and abscess with considerable accuracy. It is only in localized Jacksonian epilepsy (about 2 per cent. of all cases), that operation is indicated, and in only about 20 per cent. of these is it successful. Trephining for epilepsy, therefore, is of very limited application and is only to be recommended in a few selected cases which present the necessary guide to both physician and surgeon. In abscess of the brain, early operation as soon as the condition is diagnosed is imperative, and in cases of skull fracture or concussion, followed within two or three weeks by symptoms suggestive of abscess, even if there are no localizing symptoms, trephining is imperative. In brain tumor, with positive localizing symptoms, operative interference may be warranted, but without localizing symptoms, operation promises nothing. The proposition to afford relief in inaccessible tumors by making a considerable opening in the skull to relieve pressure, may be of value in some cases. In cases of extradural hemorrhage from traumatism, with symptoms of intracranial pressure, slow pulse, steady rise in blood pressure, deepening coma, Cheyne-Stokes respiration, and increasing hemiplegia, all appearing within six hours of the injury, trephining is sufficiently clearly indicated. In apoplexy, Cushing has applied successfully, in hospital cases, the test of the condition of the blood tension in determining the need of surgical intervention to save life. Cushing has also treated surgically with success new-born infants who, after a difficult labor, have suffered an extradural or intradural hemorrhage. It is easy in these cases to relieve intracranial pressure by opening the sutures of the parietal bone with scissors, and his success warrants urging obstetricians to consider this operation in the case of asphyxiated infants of the class described above. Obstetricians see these cases, and if they are convinced that delays are dangerous the percentage, Starr says, of idiocy and hemiplegic epilepsy will certainly be reduced. The last class of cases of cerebral hemorrhage suitable for trephining is that in which hemiplegia or hemianopsia develops slowly after an injury, and does not come to its height for three or four days. In these there is probably a surface hemorrhage from a vein in the pia mater, and lumbar puncture will probably reveal blood in the cerebrospinal fluid.

The Lancet, September 8, 1906.

Recovery from Over Forty Grains of Perchloride of Mercury.—About forty-three grains of mercuric chloride were taken by a woman patient of P. C. Maitland.

He gave about four ounces of carron oil made with cod liver oil (as the only oil available), followed by one ounce of wine of ipecac. As soon as possible milk and the whites of eggs were given. The next morning the patient was fairly comfortable, and in a day or two quite well. The time elapsing between the taking of the poison and the administration of the remedies is not stated.

A Case of Bradycardia.—C. E. McDade reports the case of a man of seventy-two years. His heart sounds were clear, urine normal, and his blood-vessels seemed healthy. At times his pulse ran down to from 32 to 40. On one occasion the radial pulse was 28, while the jugular pulsation was 56. Later the pulse became intermittent and the patient complained of a pain in the left side of the head. Several attacks of diarrhea supervened and the urine became full of water and gave a haze on boiling. Under rest and nutritious diet he gradually improved, and when last seen by the author his pulse was 72, strong, and regular. No suggestions are made as to the exact cause of the extremely low pulse rate at various stages of the case.

A Case of Intussusception Illustrating the Dangers and Fallacies of the "Inflation" Treatment.—J. L. Falconer reports the case of a male child of ten months with the usual symptoms of intussusception apparently reduced by the ordinary water inflation. The child was somewhat collapsed after the procedure, but recovered and passed nominal feces. A few days later the tumor was again felt, and was again reduced as before. Still again in a week a similar experience was gone through with except that the child began to develop a typical abdominal facies. It was removed to hospital and the abdomen opened through the right rectus muscle. A mass was found low down in the pelvis, and at first the invaginated gut was easily withdrawn, but a part was soon reached where the intussusception had sloughed through the intussuscipiens and was surrounded by a local peritoneal abscess. The mass was cut away and the divided ends of the bowel were fastened on the upper angle of the wound. A drainage tube was inserted down to the pus area. No cause could be found for the intussusception. The child collapsed ten hours after the operation and died. The operating surgeon, E. D. Telford, declares that the inflation treatment is dangerous, uncertain, useless in any variety of the lesion beyond the ileocecal valve, and not applicable when once plastic peritonitis has taken place. Early abdominal section is the most rational plan of treatment. Recovery after the trouble has existed thirty hours is very unusual in any event.

Some Remarks on the Therapeutic Action of the Iodides.—J. Burnett passes in review some of the therapeutic indications established for the use of the iodides, especially the potassium salt. First, aneurysm, though we do not positively know its mode of operation. Administration by the mouth has, in the author's experience, but little influence on the pulse rate or arterial pressure. Various authors have suggested the iodides for arteriosclerosis, but its beneficial effects are probably due to its power of increasing elimination, thus enabling the blood to get rid of irritating substances, rather than to any power to reduce arterial pressure. The iodides tend to diminish the excretion of uric acid. In angina pectoris one should give at least from forty to sixty grains of the drug daily and keep up this quantity for a long time. In chronic respiratory diseases the iodides are one of our most valuable agents. In chronic rheumatism benefit is derived from the iodides by virtue of their effect on the uric acid excretion. They serve, too, as eliminatives in case of effusion, are of service in interstitial nephritis, though considerable of the remedy is necessary to serve as an efficient diuretic. In hepatic cirrhosis, metallic poisoning, and cases of goiter they are often of benefit.

Berliner klinische Wochenschrift, September 3, 1906.

The Absorption of Dead Tubercle Bacilli.—Marmorek says that it has been regarded as a well-established fact that the animal body is not able to absorb the bodies of dead tubercle bacilli as it can those of other organisms. Experiments he has carried out seem to show, however, that under certain conditions this does not hold true and absorption is possible. On injecting emulsions of ordinary cultures of tubercle bacilli into rabbits and guinea pigs cold abscesses are always formed. The absorbability of the bacilli is greatly increased by extremely careful trituration of the cultures so that no aggregations of bacilli remain. No amount of trituration seems to render bacilli from old cultures absorbable, but carefully prepared emulsions from young cultures are completely absorbed by the experiment animals so that after a week or so it is difficult to find any of the bacilli in the tissues. The absorbability of the organisms could also be greatly enhanced by mixing the emulsion with the author's antituberculosis serum, and by this means the absorption of even the old, resistant organisms could be secured.

Münchener medizinische Wochenschrift, September 4, 1906.

An Extravesical Urine Separator.—Tromp describes an apparatus devised by Professor Heusner for obtaining specimens of urine from the two kidneys, for purposes of renal diagnosis. The author states that the various forms of intravesical separators have been found unsatisfactory, and he also recounts a list of objections to catheterizing the ureters through the cystoscope, chief of which, of course, is the danger of infection. Heusner's apparatus consists of a metal framework supporting two vertical screws bearing pads at their extremities and which are so arranged that they may be screwed down over a recumbent patient's abdomen in such a way as to exert pressure at either side of the fifth lumbar vertebra, thereby compressing the ureter as it crosses the brim of the pelvis. The bladder is first irrigated while both ureters are compressed, and then the urine first of one side and after a second washing, that from the other side is collected by manipulation of the compressing screws. It is stated that the maneuver is not very uncomfortable to the patient, and four cases are described in which it was used with very satisfactory results.

A Ring Test for Acetone.—Lange describes the following test for acetone in urine: One-half to one c.c. of glacial acetic acid is added to 15 c.c. of the suspected urine and a few drops of fresh sodium nitroprusside solution are added. A few c.c. of ammonia are then carefully layered over the fluid, and if acetone is present an intense violet ring will appear at the line of contact of the two fluids. In addition to the convenience of the method, the author claims for it the advantage that neither creatinine, alcohol, or aldehyde can give rise to misleading results. The test is also very sensitive, as it demonstrates the presence of acetone in dilutions up to 1-400 per cent.

A New Hysterical Condition Among School Children.—Schutte says that in the city of Meissen there has existed since last December a widespread epidemic among school children of a peculiar nervous affection locally called the "trembling sickness." The patients are mostly children between the ages of nine and thirteen years, girls being the most susceptible. The affection first manifests itself by a more or less protracted period of nervous unrest, which is followed by the gradual development of a trembling of the right forearm and hand, which in severe cases extends to the left side also. The seizures of trembling last from a few minutes to half an hour and recur at varying intervals, sometimes appearing also at night. The disease, it appears, has spread rapidly, the children apparently becoming the victims of a form of autosuggestion. The treatment necessitates a removal from school and rest in bed for a time, followed later on by gymnastics and open-air exercises.

Deutsche medizinische Wochenschrift, September 6, 1906.

A New Test for the Detection of Occult Blood in the Feces.—Schlesinger and Holst report the results of a comparative study of the guaiac, aloin, and benzidin tests for minute quantities of blood in the stools or in stomach contents. They conclude that the delicacy of both the aloin and guaiac tests is much increased by resorting to the procedure of Schumm, which consists in a somewhat troublesome series of extractions with alcohol, ether, and acetic acid, while when the benzidin test is carried out under these conditions it becomes too sensitive for ordinary use, as positive results were obtained even after ten days' abstinence from meat. The authors have devised the following test, which is superior in delicacy to the aloin and guaiac tests, but yet is not so sensitive as to be impracticable for clinical use. A portion of the stool about the size of a pea is rubbed up in a test tube with a small amount of water and the mixture is brought to a boil by holding in the flame for a few moments. The reagent consists of a concentrated solution of benzidin in glacial acetic acid which is made by adding as much of the benzidin as can be taken on a knife point to 2 c.c. of the acid. Ten drops of this solution are added to about 3 c.c. of 3 per cent. peroxide of hydrogen solution. To this mixture 1-3 drops of the feces emulsion are added, and in the presence of blood a bluish green or green color appears, usually in a few seconds. The authors recommend the test on account of its simplicity, its superiority

in delicacy to the aloin or guaiac tests, the absence of risk of a confusion through oxidizing ferments (which are destroyed by the boiling), and because the technique involved eliminates the possibility of faulty results due to the reagents or the test tube.

The Operative Treatment of Genuine Epilepsy.—Rinne's patient, who was operated on twelve years ago, when he was twenty-seven years old, was the victim of a severe form of true epilepsy which rendered it impossible for him to do work of any sort. After all other measures, including stretching of the brachial plexus, had failed to cause any improvement, excision of the cortical centers controlling the hand and arm was decided on, the seizures always beginning with twitchings in the right thumb and hand. The cortex was exposed and the centers in question were identified by means of electric stimulation, and an area of cortex three or four millimeters thick and 1 by 1.5 cm. in area was excised. Since that time, although the fits have not been cured entirely, they have been rendered a great deal milder so that the patient rarely becomes unconscious, and sometimes periods of six months elapse without a seizure. The patient has been able to found and conduct himself a small manufacturing business and is able to support himself and family. The author considers it an open question whether it was the excision of cortical substance or the cerebral decompression that brought about this result.

Inoculations with the Spirochæta Pallida.—Greeff and Clausen describe and illustrate positive results obtained on inoculating the anterior chamber of the rabbit's eye with luetic material. Sections of the cornea made some weeks after the infection revealed large numbers of typical spirochetes. The authors call attention to the fact that owing to distribution of the organisms through the lymph channels of the cornea it is necessary, in order to demonstrate them, to make the sections longitudinally and not transversely.

French and Italian Journals.

Neurofibromatosis with Plexiform Neuroma.—Jaboulay gives an interesting and detailed description of this growth. The patient, a man twenty-three years old, sought medical aid merely for esthetic reasons. The tumor was the size of a mandarin, flattened, and triangular in shape. It was pediculated. The mass was soft, with a surface lobulated like that of a lipoma or deep angioma. By pressing it between two fingers there could be felt tiny particles like small grains, connected by little threads. The pedicle of the tumor was condensed into a hard cord. The precise insertion of this pedicle could not be determined by palpation. The growth was not painful. It was situated on the forehead, falling down in front of the eye. The patient gave a history of the appearance of the tumor at the age of two years. It grew slowly in size for three years, when an operation was performed. Whether the operation was complete or partial, the tumor rapidly reappeared, and continued to increase slowly in size. A systematic examination of the rest of the body revealed a series of tumors and pigmentations. These tumors were all subcutaneous, and movable between the skin and the deeper tissues. The pigmentations differed in appearance in different locations. The frontal tumor was benign and congenital. This rare and curious affection is less a tumor than a malformation of the peripheral nervous system. It may persist indefinitely without affecting the general condition. However, malignant degeneration may occur. The tumor was removed and the patient went away cured, eight days later. The structure of the tumor was that of a pure plexiform neuroma.—*Gazette des Hôpitaux Civils et Militaires*, August 28, 1906.

Cholecystectomy for Cancer of the Gall-Bladder.—Patel reports this case. The patient, a woman, sixty-eight years old, was sent into the hospital on account of symptoms of intestinal occlusion. The patient had borne eight children, two only of which were living. For a year she had not been well. She had had pain in the abdomen, with vomiting now and then. There had been a little constipation. The pain became more severe some hours after eating. For two days before entering the hospital her symptoms had increased greatly in severity. Palpation of the abdomen showed resistance in the right hypochondrium. A swelling which could be felt seemed to be associated with the liver. Further examination showed the tumefaction to be continuous with the liver. It appeared hard, tense, and regular. The stomach was not dilated. The patient was extremely emaciated. Operation revealed the trouble. The gall-bladder was twice its normal size, hard, and with thickened walls. Radical operation was performed. Histological examination showed the existence of carcinoma. Nine months after operation the patient is still in good health. The writer believes that in cases of extrinsic cancer which is incapsulated in the gall-bladder, radical operation ought to give excellent results.—*Lyon Médical*, August 26, 1906.

Pulmonary Adenopathies, Anatomical, Radiographic, and Clinical Study.—Piéry and Jacques present the following conclusions: Anatomical and radiographic researches establish a distinction between pulmonary adenopathies and mediastinal or tracheal adenopathies. The first only, by their direct relations to pulmonary lesions, give indications concerning the condition of the lungs. In every pulmonary infection, tuberculous or otherwise, the pulmonary ganglia are, at autopsy, as much more developed, hypertrophied, and numerous, as the pulmonary process is more intense. Cretaceous lesions of the ganglia indicate an old tuberculosis which has been cured; sclerotic foci indicate an old tuberculosis less certainly cured; caseous foci are old foci still in the process of evolution. While tracheal adenopathies necessitate an oblique lateral examination, pulmonary adenopathies are revealed on a screen by an anteroposterior examination. The image of these adenopathies is very different, according as the lesion is recent or old. Radiographic examination allows of a diagnosis which without it would pass unperceived. It offers also a retrospective diagnosis in latent cases. Prognosis also is simplified by this method.—*Revue de Médecine*, August, 1906.

Reduction of Pseudosubcoracoid and Axillary Dislocations (Recent and Noncomplicated).—R. Rapoutova believes that in the reduction of a dislocated shoulder narcosis ought to be avoided. In typical subcoracoid dislocations, Kocher's method always succeeds. It does not require narcosis. When this method is not successful, one may rest assured that he is dealing with a psuedosubcoracoid dislocation, that is, with a secondary displacement (axillary, intracoracoid, intraclavicular). This secondary displacement is sometimes spontaneous. More often it is consecutive to attempts at reduction. In such a case general anesthesia is often indicated.—*Revue Médicale de la Suisse Romande*, August 20, 1906.

Primary Pigmented Syphiloderm.—Giuseppe Ronchi has studied eight cases of pigmented syphilitic lesion, which is generally called the collar of Venus, and has been supposed to be secondary to a previous macular or papular lesion. He states it as his belief that it occurs without any preceding lesion, and should be called a primitive pigmented syphiloderm. It occurs during the secondary period of the disease, and consists of patches of pigmented skin of a deeper color than normal, surrounded by normal colored skin, which are permanent and are located generally on the neck, although sometimes found diffused over the surface of the body and limbs. The pigment granules are found abundantly in the chromogenous layer of the skin and in the upper portion of the chorion, having origin in the epithelial cells.—*La Riforma Medica*, July 2, 1906.

Treatment of Pulmonary Tuberculosis by Acids.—Arturo Campani says that some authors have founded on the fact that in the pretubercular period and in early tuberculosis there is a lessened acidity of the urine, the theory that the proper medication for such patients is the administration of acid phosphates to maintain the acidity in the body. The author has studied the urinary conditions in twelve tuberculous patients; of these, five were in the early stages, without fever and with slight physical signs, but weak, and with rapid pulse; two were marked cases, but in good physical condition; the remaining five were so far advanced as to be confined to bed. As a result of his observations he believes that there is a noticeable lowering of the acids of the urine in early cases that are of low vitality and have frequent pulse. This is rare in those who are strong and have a normal pulse. In febrile cases the acids are above normal. This condition is not due to a lowering of the acids in the body, but to an increased excretion of alkalies, and a medication directed to increase the acids taken is useless to cure or prevent the disease.—*Giornale Internazionale delle Scienze Mediche*, June 30, 1906.

Diverticula of the Appendix.—Weinberg has observed two new cases of diverticula of the appendix. The study of these cases shows that these diverticula owe their origin to an abscess having its beginning in a suppurative lesion of a lymphatic follicle. This extends into the submucosa and even into the muscular layer of the wall of the appendix, above and below the initial lesion. When the abscess is cured there has been formed in the wall of the appendix a cavity parallel to the lumen of the organ, with which it communicates at one point. This can easily be noted by examination of the serial sections. In one of the cases in which the appendix was divided into two cavities by a partition of inflammatory origin, the diverticulum was formed in the lower half of the organ. Mucus secreted by the glands of Lieberkühn accumulated until the entire diverticulum was filled up with a plug of condensed mucus.—*La Presse Médicale*, June 27, 1906.

Book Reviews.

THE SUBCONSCIOUS. By JOSEPH JASTROW, Professor of Psychology in the University of Wisconsin. Boston: Houghton, Mifflin and Company, 1906.

THE phenomena of man's subconsciousness are of the greatest practical, as well as scientific, interest to the physician who would know every wheel in his patient's mental mechanism and understand every phase of normal and abnormal brain activity. Jastrow's book presents in attractive semi-popular form an analysis of the normal and abnormal subconscious phenomena. The first part deals with definitions and with the relation of subconsciousness to mental processes; with lapses of consciousness and self-consciousness in normal persons. The second part is devoted to a study of abnormal subconscious states, to dream consciousness, and to dual or altered personality, etc. Professor Jastrow has handled an interesting but difficult subject in a manner which must excite admiration. His style is one flowing fount of scholarly yet lucid English, and the reader's grasp of the subject-matter is made easier by a considerable number of cited cases.

MANUAL DE PRACTICA SANITARIA PARA USO DE JEFES E INSPECTORES DE SANIDAD, Dirigido y Anotado por el Dr. ENRIQUE B. BARNET, Jefe Ejecutivo del Departamento de Sanidad de la Habana. Habana: Departamento de la Sanidad, 1905.

THIS official manual of sanitation is issued by the Department of Health of the Cuban Republic. It contains a series of articles covering the entire range of hygiene, sanitation, etc., by a number of the principal officials of the Cuban Health Department. The volume is attractively got up and well illustrated. The first part includes the contagious diseases that must be reported. The second deals with the organization of the Health Department, sanitary engineering, mosquitos, vaccination, sanitation of tenements, hotels, theaters, etc., of hospitals, barracks, schools, and the special regulations concerning noxious trades. The hygiene of drinking water, disinfection, the analysis of foods, form another group of chapters. A chapter is also devoted to the science of vital statistics, one to quarantine, and the regulation of immigration. A description of the public laboratory of Cuba and of Las Animas Hospital, and a compilation of the sanitary laws complete the volume. The book will doubtless serve as a model of its kind for the various Spanish-American countries. It represents the constant advances in sanitation shown in Cuba under the republican régime.

ÉTUDE CLINIQUE ET TRAITEMENT DE LA LITHIASE DU CHOLÉDOQUE. Par le Dr. RAYMOND FRANÇAIS, Ancien Interne des Hôpitaux de Paris. Paris: Steinheil, 1906.

FRANÇAIS' thesis concerns itself with the clinical features and the surgical treatment of gallstones of the common duct. The 18 cases cited are taken from the service of Professor Hartmann, and a set of well-drawn line sketches illustrates the various steps in the operations for the relief of the condition dealt with. The best chapter in the book is that dealing with the technique of choledochotomy. Nothing strikingly new is offered by Français save the account of the 18 cases mentioned, fifteen of which were operated upon by choledochotomy. This group of cases then must be added to the 202 cases of Kehr, the 180 cases of Schott, the 137 cases of the Mayo Brothers, etc. Of Hartmann's patients whose cases are here reported four died, of whom two died 6 months and 3 years respectively after operation, while of the remaining two one died of peritonitis and the other on the eleventh day, probably of angiocholitis. The introduction of a drain into the duct after opening it is insisted upon as an important feature, while Mayo-Robson's hyperextension is regarded as essential in operating.

MODERNE PHTHISIOGENETISCHE UND PHTHISIOTHERAPEUTISCHE PROBLEME IN HISTORISCHER BELEUCHTUNG. Von Prof. E. VON BEHRING, Wirklichen Jeheimen Rath. Berlin: August Hirschwald, 1906.

THE present eleventh number of the Beiträge zur Experimentelen Therapie, edited by von Behring, is devoted to a discussion of the modern problems of tuberculous pathogenesis and therapy, viewed in a two-fold light: in that of history as reflected in the works of Baillie, Vetter, Bayle, Laennec, Lebert, Morgagni, Villemin, Virchow, Cohnheim, Koch, and Aufrecht, and in that of Behring's own experimental researches. The purpose of the book is to prepare the medical world for the discovery of the new specific against tuberculosis to be known as "Tx," which Behring promises to announce before the end of the present year. This tuberculosis remedy will not contain the bodies of germs as does Behring's bovovaccine. By a special treatment of living tubercle bacilli Behring extracts from them Tc, a residual powdered substance which when injected into the tissues produces noncaseating, self-limited tubercles. Tx, the promised new remedy, is a preparation derived from Tc, which is an immunizing vaccine in man but is said to be harmless. The second part of the book, dealing with therapeutics, will contain further details of this new remedy.

UEBER DIE STIMMUNGSSCHWANKUNGEN DER EPILEPTIKER. Von Prof. Dr. GUSTAV ASCHAFFENBURG, in Köln. Halle: Carl Marhold, 1906.

ASCHAFFENBURG'S essay deals with the "emotional equivalent" of epilepsy, *i.e.* of the periodic variations in mood observed in some epileptics. The questions which he considers are: (1) Are these periodic variations in emotional mood characteristic of epilepsy, and, if so, (2) in what manner do they differ from emotional anomalies in mentally diseased persons in general? The first question is answered affirmatively; the second is briefly discussed in an attempt to characterize the special features of emotional variations in epileptics. The author's style is exceptionally free from the diffuseness and topheaviness so characteristic of many modern authors on such themes as this.

NOUVEAU TRAITÉ DE MÉDECINE ET DE THÉRAPEUTIQUE. Publié en Fascicules sous la Direction de MM. P. BROUARDEL et A. GILBERT, Professeurs à la Faculté de Médecine de Paris. X. STREPTOCOCCIE, STAPHYLOCOCCIE, PNEUMOCOCCIE, COLIBACILLOSE, par F. WIDAL, J. COURMONT, L. LANDOUZY ET A. GILBERT. Paris: J. B. Baillière et Fils, 1906.

THIS tenth fascicle of Brouardel and Gilbert's new system of medicine deals with streptococcus, staphylococcus, colon bacillus, and pneumococcus infections in their various forms. The streptococcus, its bacteriology, pathogenic effects, etc., is handled by Widal, who describes in especial detail erysipelas of the face. Courmont has charge of the chapters on the staphylococcus. Landouzy writes on the pneumococcus, and Gilbert on the colon bacillus. Nothing new is presented as to the treatment of facial erysipelas. In speaking of serum therapy against the pneumococcus the authors are sceptical and declare that a serum which immunizes against one culture of the germ does not seem to have any effect against another sample. The illustrations are simple diagrammatic cuts.

A COMPEND OF MATERIA MEDICA, THERAPEUTICS, AND PRESCRIPTION WRITING, with Especial Reference to the Physiological Action of Drugs. Based on the Eighth Revision of the U. S. Pharmacopœia, Including also Many Unofficial Remedies. By SAMUEL O. L. POTTER, M.D., M.R.C.P. Lond., Formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco: Author of "Materia Medica, Pharmacy, and Therapeutics," "Quiz Compend of Anatomy," etc. Seventh Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son and Company, 1906.

POTTER'S compend on Materia Medica is so well known that it is only necessary to draw attention to this new edition, which has been thoroughly revised and brought into conformity with the eighth edition of the U. S. Pharmacopœia. Wherever necessary, new articles and paragraphs have been inserted, and obsolete matter removed. The essentials of the subject have been kept in view throughout, and the book is one of the best compends on Materia Medica in the market.

ON CARBOHYDRATE METABOLISM. A Course of Advanced Lectures in Physiology Delivered at the University of London, May, 1905. With an Appendix on the Assimilation of Carbohydrate into Proteid and Fat. Followed by the Fundamental Principles and the Treatment of Diabetes Dialectically Discussed. By F. W. PAVY, M.D., LL.D., F.R.S., Honorary Physician to King Edward VII. Hospital; Consulting Physician to Guy's Hospital. London: J. and A. Churchill; Philadelphia: P. Blakiston's Son and Company, 1906.

THE contents of this volume are sufficiently indicated by the title, which declares it to contain three chapters, all dealing with subjects of prime importance to the student and practitioner. Carbohydrate is discussed from both its physiological and its pathological side, the author urging that a knowledge of the physiological operations involved in carbohydrate metabolism constitutes a necessary preliminary to a right comprehension of the pathology of diabetes. The author's views on the doctrine of glycogenesis are well known and will be found fully set forth in these pages. Quite early in the book he gives a refutation of the generally accepted ideas on the subject, and later on he shows that a misunderstanding of the subject gives rise to erroneous teachings on the dietetic treatment of diabetes. Such new theories as the author has to offer are thoroughly worked out, clearly set forth, and backed up by both laboratory experiments and clinical experience. All students will welcome the veteran author's latest contribution to this subject.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-sixth Annual Meeting, Held at Bedford Springs, September 10, 11, 12, and 13, 1906.

(Special Report to the MEDICAL RECORD.)

GENERAL SESSION.

Tuesday, September 11—First Day.

THE meeting was called to order in general session at 9.30 A.M. by the President, Dr. William H. Hartzell of Allentown. Prayer was offered by the Rev. M. L. Culler of Bedford. The presentation of the program was made by Dr. Simon H. Gump of Bedford, Chairman of the Committee of Arrangements, and Dr. W. P. S. Henry of Everett, President of the Bedford County Medical Society, gave the Address of Welcome. Dr. C. L. Stevens of Athens, Secretary, spoke briefly of the state of the Society.

President's Address.—Dr. WILLIAM H. HARTZELL, in his address, spoke of the increase in membership of the State Society as compared with nineteen years ago, the number of members having increased from about 800 to 4,600. He made a plea for a continued and persistent effort in organization for the improvement of the profession. He suggested that every school district within the State would be provided with a committee to instruct the public by means of lectures and leaflets regarding measures for the relief and control of tuberculosis. An earnest plea was made also for a pure water supply and isolation of contagious diseases. He dwelt upon the injury done to the profession by free hospitals and dispensaries. Another evil that called for correction was the neglect of the physicians in their accounts and collections. The contracts between physicians and lodges, casualty companies and corporations, he condemned, and urged that every county society take this matter up and remedy the evil. "It is a matter of professional pride," he said, "that in the general condemnation of the life insurance companies, although every other part of the control has been shown to be corrupt, no breath of scandal has touched the medical department." In conclusion Dr. Hartzell pointed out some of the principal advances in internal medicine, surgery, diagnosis, and therapeutics.

A Plea for the Creation of a State Hospital for Inebriates and Drug Habitues.—Dr. THEODORE DILLER of Pittsburg said that the present legislation upon this subject largely failed of its beneficent purpose, because the "proper hospital or asylum" does not exist within the borders of the State. He argued the great need of a special institution for inebriates, owned and operated by the State, to which pay patients as well as indigent patients could be committed. Quotations were made from letters received from T. E. McGarr, Secretary of the New York State Commission in Lunacy, and Dr. William Mabon, expressing the belief that a properly equipped hospital for inebriates, owned and operated by the State and governed by proper laws, was badly needed. In Iowa a specially equipped hospital was operating under a wise and strong law, and, although not perfect, was doing great good. The provisions of this law were given. That the inebriates of the State were largely left to the devices of the various "cures" owned by cunning proprietors, seemed a reproach to the public as well as to the medical profession. To the correction of this Dr. Diller suggested that the Medical Society of the State of Pennsylvania take the initiative in appealing to the Legislature to create a special hospital for inebriates to make its present law effective, believing it to be the duty of the Society to point out the proper method of treating inebriates.

Dr. JOHN B. CARRELL of Hatboro attributed inebriety largely to temperament and to wrong ideas of sociability. He was firmly of the opinion that an inebriate hospital should be established in Pennsylvania.

Dr. LOWELL M. GATES of Scranton agreed with Dr. Carrell that a person of nervous excitability was more susceptible to inebriety than the phlegmatic man taking beer regularly. He felt that there was little hope of cure with the present conduct of the saloon, which endeavored to make a man drink. He did not believe treatment extending over two or three years was necessary, but held that a man's desire to drink could be removed in from twenty-four to forty-eight hours.

Dr. CHARLES K. MILLS of Philadelphia said that laws had not been evolved sufficient to deal with the problem of the care and treatment of the inebriate; incomplete legislation, however, was better than none The first essential was a better law in regard to the seclusion of the inebriate. The institution for this purpose need not be a very large one, but should be capable of expansion. While he did not believe that an inebriate could be successfully treated in so short a time as a day or two, three years he thought unnecessarily long.

Dr. CHARLES W. BURR referred to the injustice of the present law on account of its provision for the well-to-do and not for the poor, since it required the giving of a bond for the board of the patient committed. He felt that the failure of the successful treatment of inebriates in insane asylums was due to the manifold duties of the physicians in charge. He believed also that it might possibly be better if the care of inebriates were undertaken by private institutions, rather than left to the oversight of the State. The chances of cure for the inebriate, in the true sense of the word, Dr. Burr felt to be very small, but believed cure possible in those who through idleness had acquired the habit.

Dr. F. W. FRANKHAUSER of Reading inquired why, if the percentage of cure of inebriety were so small, it would not be better to prevent it. Under the present legislation the revenue from the saloons and breweries was used to pay for the care of just such cases as they produced. The better plan, he urged, would be to prohibit the conditions which made men and women inebriates.

Dr. HENRY BEATES of Philadelphia thought it self-evident that a man addicted to narcotics and unfit for the duties of life should be placed under some influence—call it a school or a hospital—which would so strengthen him in self-control that his will would be stronger than the temptation.

Dr. JOHN B. ROBERTS said he had always thought that he would like to understand neurology, but was free to say that if neurology made one so hopeless as Dr. Burr appeared to be, he did not care to know anything of it.

Dr. LOWELL M. GATES of Scranton thought that the medical profession had added to the number of inebriates by the careless prescribing of alcohol to those who might be run down in health.

Dr. Diller closed the discussion, and on motion the subject was referred to the House of Delegates.

SECTION ON MEDICINE.

Tuesday, September 11—First Day.

Oration on Medicine.—Dr. DANIEL W. JEFFRIES of Chester delivered this oration, in which he spoke of what might possibly be called the decadence in the general practice of medicine. A noted surgeon might come to this country to give professional service, and the whole population of America was stirred, whereas any number of general practitioners of medicine might light upon American shores and no one know anything of it. Notwithstanding this, he declared it to be the general practitioner who did the major part of the work in medicine in this country. He deprecated the fact that by some the medical books of two or three years' standing were considered not up to date. Percontra he mentioned books published in 1840

and 1856, than in which better descriptions of disease and methods of diagnosis could not be found in the present-day publications. While he was in favor of "holding fast to that which is good," he was also in favor of "not letting go of that which was good in the past."

Some Causes of Inefficiency in Medical Practice.—Dr. John B. Roberts of Philadelphia read a paper with this title, the topics discussed being "lack of equipment for prompt service," "carelessness in observation," "indefiniteness in giving orders," "want of self-confidence and tact," "failure to appreciate the value of common remedies," and "insufficient doses of medicine." The physician anxious to serve, and perchance save his patient, should see that he always had professional tools with him; a doctor who had to send for any of the necessities of his calling before he could relieve agony, had better be a plumber or a carpenter, such mechanics being notorious for returning to the shop for tools before the work can be done. Many mistakes in diagnosis and treatment were attributed to hurried and careless examination. Only an inefficient doctor would tell a short-breathed patient that he had asthma when there had been no analysis of the urine or auscultation of the chest. An efficient practitioner must ever be keen keen-eyed, open-eared, and wide awake, and could not afford to have his intellectual acuity blunted by beer, tobacco, or unnecessary loss of sleep. To kill a man by bursting his intestine with a large enema given by hydrostatic pressure from a high level was mentioned as a professional tragedy, which might occur from lack of definite instructions to a subordinate. Repose, and the modest but confident voice of self-reliance, were cited as mighty aids to successful control of the sick. As a horse feels through the bit the character of his driver, so the keen invalid might know the character of his doctor by seeing him enter the room. Clean air, clean water, clean food, and sound sleep, though the cheapest of all remedies, were said to be the most neglected. The importance of exercise was emphasized; better to scrub the back yard with a broom than to depend on a rubber for exercise and the druggist for one's appetite.

A Discussion of Some of the New Features of the United States Pharmacopœia of 1900.—Dr. Adolph Koenig of Pittsburg attributed the cause of the unpopularity of the U. S. Pharmacopœia to the medical colleges. As example of the general unfamiliarity errors were cited in nomenclature in the writing of both old and recent graduates in which the name of the principal alkaloid of opium was designated as "morphia" in place of the official title of "morphina," in spite of the fact that for twenty years or more the former title had been obsolete. Bearing upon the advantage of using the official rather than the proprietary names, it was stated that in the open market one of the newly-admitted drugs cost $2.50 per pound when brought under its pharmacopœial name, while under the various copyrighted names it cost from $4.80 to $12.80 per pound. Attention was called to the changes due to the demand for uniformity in nomenclature of drugs, one of the most important of which was that of the fluid extracts.

Dr. Max R. Goepp, in referring to the remarks of Dr. Jefferis, thought that the specialist was as necessary to the general practitioner as the general practitioner to the specialist.

Dr. Judson Daland referred to the necessity of the specialist and the general practitioner working together, saying that in every man's practice there came a time when he needed special advice.

Dr. John W. Boyce of Pittsburg did not believe the general practitioner a bad fellow, nor did he believe the general public thought so. Specialism, he thought, had been abused.

Dr. E. V. Swing of Coatesville thought that the "passing of the family physician" had not yet occurred.

Dr. Rigg of Wilkinsburg said that he belonged to the class of general practitioners, and therein expected to continue. Every one, however, respected and honored a good specialist. The difficulty lay in the abuse of specialism.

Dr. Seneca Egbert of Philadelphia challenged a statement that medical students were not at the present time being taught to write prescriptions.

Dr. Wendell Reber of Philadelphia attached more value to the United States Dispensatory than to the Pharmacopœia.

Electricity in the Treatment of Disease.—Dr. John V. Shoemaker considered a few of the applications of electricity especially serviceable in his experience, and commented upon the proper field of usefulness of this potent force. Any preconception of electricity as being a mystericus, life-giving force, capable of working miracles, should be dissipated. It was pointed out that while electricity was always the same in itself, it might be applied in different modes producing different therapeutic results It was observed that electricity might be used to produce, among other effects, local necrosis, disturbance of the electrical relations of the elements of nerves and muscles, to modify metabolism, to act as a temporary stimulant to nutritive processes, and to produce magnetic effects. Of most importance was the fact that electricity, in most cases, was to be regarded as only an adjuvant to other treatment.

Treatment of Four Cases of Pulmonary Tuberculosis in Advanced Stages with High-Frequency Electricity.—Dr. M. L. Barshinger of York presented reports of four cases of pulmonary tuberculosis, showing excellent results of this treatment, even in the advanced cases. A complete record of pulse and temperature at the time of each treatment, and statements of patients themselves in reporting their condition at each visit; also a description of the apparatus used, and the author's observations and conclusions of the action of the current in this disease. It was suggested that the treatment might be used with advantage in sanatoriums in connection with the other usual methods.

The High-Frequency Currents in Chronic Rheumatism and Rheumatoid Arthritis.—Dr. G. E. Pfahler of Philadelphia, in the presentation of this paper, claimed that the high frequency currents were not injurious to the human organism, that while they were not painful, a sensation of warmth was produced by their action, respiratory combustion was increased, and the quantity of oxygen consumed in a unit of time, as well as that of the carbonic acid eliminated, was heightened. This augmentation of the process of combustion was also indicated by the increase in the amount of urea excreted, while the uric acid was diminished. Since chronic rheumatism and rheumatoid arthritis were probably due to faulty metabolism, high frequency currents were indicated. Mention was made of one case of well-advanced rheumatoid arthritis, with a very bad hereditary history, which recovered complete use of all of the joints. Since in chronic rheumatism the pains and the stiffness, which were the chief symptoms of this disease, were relieved by high frequency currents, the treatment was here indicated

Dr. Jay F. Schamberg spoke of the relation of the high frequency currents and allied therapeutic measures in connection with the pigment of cutaneous diseases.

Dr. Matheeny of Pittsburg said he had had a limited experience with the high frequency current in his office, and had found it beneficial in some cases of glandular enlargement. The cost of the current was mentioned as a question of practical importance.

Dr. C. C. Miller of Altoona believed that while electricity could benefit disease to a large extent, it should not be regarded as a specific for any disease.

Dr. Charles K. Mills of Philadelphia had seen a striking illustration of the relief of pain, apparently arthroidal, from the use of the *x*-ray, and in the condition known as "typhoid spine" he had known of marked relief

from the use of either the *x*-ray or of the high frequency currents.

Dr. Lawrence Litchfield cited cases in his own practice which had been markedly relieved by electrical treatment. He felt that the subject of electrotherapy was not regarded quite as favorably as it should be by the general practitioner.

Dr. Seneca Egbert of Philadelphia referred to the fact that in the high frequency current there was encountered a force very analogous to light, and that as in electricity and light two of the most wonderful forces of Nature were presented, it was the part of wisdom not to adopt a nihilistic attitude toward these agents.

Dr. Pfahler, in closing, emphasized the importance of looking upon these agents fairly, and of simply accepting the facts as they are presented. So far as he knew there had never been a satisfactory explanation of the relief of pain caused by the *x*-ray. All the other effects of the *x*-ray had been proven by a number of methods to be due to a chemical action. The fact remained, however, that the relief of pain was wonderful.

The Diagnosis of Brain Abscess.—Dr. John W. Boyce of Pittsburg reported nine cases. Of individual important symptoms, temperature was first considered; neither a continuous nor a remittent temperature, however, would establish or exclude abscess. Observation of the pulse was regarded as important. Tension was considered important, and only in this department of practical medicine did he regard the sphygmomanometer an absolutely indispensable instrument. While the leucocyte count was always of value, it might fail in any individual case. The mental state was said to be often characteristic, and might lead an alienist to advise exploration.

Dr. William G. Spiller said that most of the cases of brain abscess which he had seen had been due to otitis media. If the symptoms warranted the diagnosis of intracranial lesion, operation was imperative.

Dr. Charles K. Mills said he had been impressed with the facts that the diagnosis of cerebral abscess for the purpose of operation was largely made by a close study of the focal lesion plus the indications pointing to middle ear or other purulent disease, and plus the absence of indications pointing to the sinus thrombosis or tumor.

Dr. Boyce, in closing, said that doubtless many cases of brain abscess died without the practitioner suspecting that there was anything for the neurologist to do.

An Analysis of the Kidney Condition of 1,000 Cases of Scarlet Fever Treated by Routine Doses of Chloral Hydrate.—Dr. B. Franklin Royer of Philadelphia presented an analysis of the kidney condition of 300 patients treated by routine doses of chloral hydrate given during the febrile period and continued for several days after all fever subsided, paralleling this analysis with a similar group of 756 patients treated with the usual remedies used in this disease. His study showed an incidence of 5.50 per cent. post febrile nephritis where chloral was used and 7.76 per cent. where chloral was not used, giving an apparent saving of 2.17 per cent. of post febrile nephritis. He presented tables showing detailed analyses of the kidney condition of each group of cases, and concluded that chloral hydrate is of distinct value in the treatment of scarlet fever, and when used in doses of sufficiency to secure light somnolence, does not seem to be a circulatory depressant; that it ameliorates nervous symptoms better than any remedy yet suggested in the treatment of scarlatina; that it allays the itching of the skin; that when given routinely during the febrile period and for some days thereafter post-febrile nephritis appears to be less frequent. This study in his opinion seemed to justify the more extended use of chloral in the treatment of scarlet fever, and a more detailed study of its action on the kidney itself.

Dr. Rigg of Wilkinsburg said that for a number of years he had been much interested in the subject considered by Dr. Royer, and that, although he had not kept detailed records, he could endorse the findings presented. Scarlet fever had been less severe, less fatal, and less liable to complications when chloral hydrate was used than in the employment of any other treatment.

Dr. Royer, in closing, stated that in no case did he make his diagnosis of nephritis on the presence of albumin alone, nor did he diagnose nephritis in the earliest stages from one or two purely hyaline casts and albumin.

Second Day—Wednesday, September 12.

Pernicious Anemia with Jaundice.—Dr. John G. Wilson of Montrose reported the case of a woman, aged fifty-five years, who had been ill about three months. The blood was thin and almost black. The stomach contents showed normal amount of hydrochloric acid present. Jaundice developed about a month before death, and gradually deepened until the patient became a golden hue over the entire body. The liver was normal in size; the hepatic ducts were distended with bile; there was no stone in the ducts or gall-bladder.

The Trained Nurse in the Public Schools, as a Factor in the Education of Children.—Dr. Solomon W. Newmayer of Philadelphia enumerated the benefits following the work of the medical inspectors and trained nurses in the schools of Philadelphia.

Dr. H. H. Herbst of Allentown spoke upon the advantages of the work of the medical inspector in the public schools in deciding questions arising between the parent and the teacher concerning the attendance of the children when the condition of their health was in question. He approved the provision by legislation for the establishment of the medical inspection system in the schools.

Dr. Seneca Egbert of Philadelphia favored the work of the medical inspector and of the trained nurse as well. An effect not so immediate but as important was, in addition to the oversight of the children, the education of the parent in matters of sanitation.

Dr. T. D. Davis of Pittsburg spoke of the danger of taking from the time to be devoted to the studies of the children, if so much attention were given to the physical condition of the children.

Dr. Myer Solis Cohen of Philadelphia agreed that medical inspection should not interfere with the education of school children, but thought that when it did, it was owing to method rather than to the fact of the inspection.

Dr. Jay F. Schamberg argued that medical inspection of schools not only preserved the health of the children, but prevented the spread of disease, and that if properly carried out might be performed with a minimum disadvantage and interference with the school duties.

Dr. Daniel W. Jefferis of Chester spoke of the great importance of the preservation of the health of the children. While much money might be spent in dispensaries, hospitals, and epileptic institutions, more could be wisely spent in the prevention of defection. He felt that a rigid inspection of the schools by physicians should be enforced, and considered the service of a trained nurse a great advantage.

Dr. James H. McKee referred to the plan of the medical inspection in the Philadelphia schools as laid out by Dr. Charles A. Codman and himself, in whose hands the work had been placed by Dr. Martin. The addition of the trained nurse had been a distinct improvement.

Smallpox.—Dr. John W. Ellenberger of Harrisburg read a paper upon this subject, which was illustrated with lantern slides. The paper was fully discussed by Drs. Jay F. Schamberg, William M. Welch, Seneca Egbert, and B. Franklin Royer of Philadelphia. A resolution was passed that the Medical Society of the State of Pennsylvania reaffirm its confidence in the prophylactic power of vaccination against smallpox, and urge the Committee on Public

Policy and Legislation to resist any efforts that may be made to weaken the present vaccination laws of the State.

Latent Diphtheria a Public Health Problem.—Dr. Myer Solis Cohen of Philadelphia, in presenting this paper, said that the latent form of diphtheria, in which the only symptoms were redness of the fauces, slight tonsillitis, nasal catarrh, an increased pulse frequency, an irritable heart or a headache, was as dangerous to the public health as were those forms with definite membrane. He recommended that cultures be taken from the throat of every child who had tonsillitis or who had been exposed to diphtheria, and that all cases in which the Klebs-Loeffler bacilli were found should be placed under the control of the health authorities.

Dr. B. Franklin Royer spoke of the many cases supposed by some to be latent diphtheria, but which were simply cases harboring germs resembling the diphtheria bacilli.

Quarantine.—Dr. Andrew B. Brumbaugh of Huntingdon called attention to a few matters contained under the general head of quarantine. In the course of his remarks he said that all colds were the result of contagion, due to a germ, the character of which no one had yet been able to determine. Every case of cold, therefore, should be carefully guarded, and the public should be educated to protect itself against this class of affections, which he held to be more destructive than smallpox or typhoid fever.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, Held at Salt Lake City, Utah, August 30 and 31 and September 1, 1906.

The President, Dr. M. L. Harris of Chicago, in the Chair.

President's Address.—Dr. Harris, in his address, departed somewhat from the custom of his predecessors of presenting a purely surgical subject for consideration, in order to take up a matter of a more general nature, yet one which he believed to be of the greatest practical importance. He referred to the question of testimony and evidence in medicine. The physician must recognize the possibility of error in the testimony of those who have every reason and intention to be honest. Therefore, in receiving knowledge of facts from others, one should be influenced by their accordance with facts previously known or believed, and this constituted what was termed their probability; but in being influenced, one must guard against two sources of error, namely, unbounded credulity and unyielding skepticism, for the former was the attribute of a weak mind, which seldom thought or reasoned, while the latter belonged to those who found nothing probable beyond their own limited field of observation and experience. That those things which accorded with one's own observations were more readily believed than those which did not, was quite natural, and thus the value of a wide experience became evident. Testimony and evidence were by no means the same. There might be a great deal of testimony, yet very little evidence. By evidence was meant "the means by which any alleged matter of fact, the truth of which is submitted to investigation, is established or disproved." This was the legal definition, but one which conveyed a better idea of the meaning of evidence as applied to medicine or the investigation of natural phenomena was that evidence in any fact which, when presented to the mind, effected or tended to effect a conviction concerning the existence of some other fact. This did not presuppose or assume any certain conclusion, but left the conclusion to be that which the evidence warranted. The value of the evidence in establishing the facts as such in any particular case varied greatly. Most of the testimony of patients was presumptive evidence of the disputable variety, and while the presumption was usually that the statements made were true, this was by no means always the case. For instance, in the case of a young woman with suppression of menstruation and an enlarging abdomen, experience had shown that the incentive to mislead was so great that the presumption was entirely in favor of the testimony being false. In medicine, he said, there were many hypotheses which were of the greatest value in enabling us to develop the facts, but when we came to the practical application of our knowledge to the individual case or to the giving of testimony before courts and juries, we should learn to recognize and to distinguish the assumed, the inferred, and the hypotheses, so as to confine ourselves to the known facts and the warrantable conclusions derivable therefrom.

Gastrointestinal Ulcer.—Dr. H. D. Niles of Salt Lake City referred to the causes and symptoms of gastrointestinal ulcer, and said that in developing our knowledge of this lesion we must bear in mind that ulcer was not only a producer of symptoms, as a primary lesion, but as the antecedent of many grave complications and sequelæ it might indirectly cause a great variety of puzzling symptoms, which the surgeon must try to interpret correctly. So long as in the consulting room and at the bedside of patients physicians permitted themselves to think of gastrointestinal ulcer simply as a theoretical possibility, of rare occurrence and obscure pathology, the symptomatic treatment would prevail, and unsatisfactory results would follow. As soon as we learned to appreciate that ulcer was not only a real pathological entity, but that it was the most common of all gastrointestinal lesions, a producer of distressing symptoms, and a forerunner of dangerous complications, we would find ourselves very near the true explanation of many obscure chronic abdominal symptoms, and we would be prepared to formulate a timely and rational treatment for the pathology that produced these symptoms.

Dr. Andrew C. Smith of Portland, Ore., said that gastrointestinal ulcer was common. It was a pathological entity that should be considered in all conditions of chronicity of abdominal symptoms. Formerly these cases were treated expectantly and continuously for long periods of time, practitioners not realizing the pathological condition. In the great majority of cases of chronic abdominal affections, gastrointestinal ulcer was and should be considered the prime lesion.

Dr. W. W. Grant of Denver said that gastroenterostomy for ulceration of the stomach and intestine, particularly the duodenum, and for obstructive lesions of these parts, was now one of the most common and conservative of modern operations. Like most new surgical triumphs, it was likely to be somewhat abused before it reached its proper status as a surgical procedure. Surgeons should be a little more conservative in the surgical treatment of these conditions, and not until there were manifest evidences of ulcer was it desirable to perform this operation. A large number of these cases were attended with a profuse acute hemorrhage. In many of the chronic cases the hemorrhage was not manifest, but the investigations of Rosenthal and Frederick showed that in these cases there was occult hemorrhage. This was shown chiefly by microscopical examination of the contents of the stomach and of the fecal discharges. When this condition existed and persisted, operation was unquestionably demanded. Operation, however, should not be undertaken until medical treatment and other non-surgical measures had had a reasonable trial.

Dr. B. B. Davis of Omaha said that in a number of instances of ulcer of the stomach and duodenum he had been able to get a definite idea as to the location of the ulcer by distending the stomach, whereas before this he was absolutely at sea. Whenever there was suspicion of ulcer either of the stomach, the duodenum, or intestinal tract lower down, the physician should resort to systematic daily examinations of the stools for blood. In a number of instances he had been able to arrive at a definite idea in this way.

whereas if he had been content with gross inspection simply he never would have suspected what had existed.

Dr. JOHN C. MORFIT of St. Louis said there was nothing that he admired more than radical conservatism. He liked to see a man who could use his head without using the knife, but who never used his knife without using his head. The greatest point in regard to gastrointestinal ulcer was not the operation; it was the diagnosis. Gastroenterostomy had been so perfected that it was now a comparatively simple procedure, and for that reason men with surgical tendencies might operate sometimes because they could, and not because they ought. He would hesitate to operate in a case of gastric ulcer until the patient was seen by a good internist and a good neurologist as well.

Dr. E. F. ROOT of Salt Lake City said it ought to be made plain to the general practitioner that ulceration of the bowel was very much more frequent than was previously supposed. General practitioners, men who were not doing very much surgery, not seeing the actual condition, were liable to have a vague impression of what was going on within the abdomen. If gastrointestinal ulcer was diagnosed, it should be dealt with surgically as soon as possible.

Dr. R. C. COFFEY of Portland, Ore., said that these ulcers were the seat of cancer in a very large proportion of cases. We had also learned that ulcer and cancer occurred in the same location. We had learned by observation that this location was where the gastrointestinal contents were detained for some reason or other. Ochsner had been working on the duodenum, and he thought that the duodenum was one among other locations for ulcer. We rarely saw ulcer at that point until we reached the cecum. A frequent seat for cancer was the cecum. Fecal matter was detained here for a while, then it passed over until it reached the sigmoid. Very rarely was cancer found at the splenic flexure, at the hepatic flexure, or in the transverse colon. The next frequent point for ulcer and cancer was the sigmoid; finally the rectum.

Dr. Niles, in closing, said that the first and most important step in our progress in this line of medicine was to realize the frequency of ulcer and to diagnose the acute pathology. The means of treating it would be taken up later.

The Surgical Treatment of Splanchnoptosis.—Dr. B. B. DAVIS of Omaha presented a brief statement of the anatomical changes found, and described the various surgical procedures which have been proposed and carried out for the relief of this condition. He gave a résumé of his own operations. He considered the relative merits of the several operations done, and discussed the value of surgery in extreme cases.

Late Phlebitis Following Clean Abdominal Operations.—Dr. W. W. GRANT of Denver presented that form of phlebitis culminating in the veins of the legs, which was known to occur most frequently about two weeks after simple, aseptic abdominal operations, without being preceded by faster pulse, elevation of temperature, pain, or any indication at present recognized of its advent. In the great majority of cases it culminated in the vessels of the left leg, no matter where the incision was made. He quoted at length from the literature, and showed that the etiology of this condition was still very hazy. His belief was that the cause of phlebitis of the epigastric, iliac, femoral, saphenous, and tibial vessels, occurring late after a perfectly aseptic operation, and clean, prompt healing of the wound, was probably not septic, with our present knowledge of pathogenic bacteria and their actions. The specific cause or causes were unknown. The cases, of which a good illustration was reported, were very difficult of satisfactory explanation. In the absence of convincing or pathological evidence, and in the face of profound surgical skepticism, it was not rational in the best and cleanest days known to surgery to assume infection that was devoid of satisfactory evidence. The condition which caused thrombosis before an inflammation, or the phlebitis preceding a thrombus, was the vital question. It was exceedingly difficult, in fact quite impossible, to reconcile the facts with the recumbent position, the simple ligature, or injury to small veins, in a distant field on the opposite side of the body, although admitting that infection might not come from the site of operation. The author believed there was a general condition affecting the composition of the blood that might be caused before operation, which was an essential factor in the cause of thrombophlebitis in these cases. A careful scrutiny of patients should be made before operation, and an examination of the blood made before and after operation. If the patient was chlorotic and anemic, or the conditions not satisfactory, the health should be improved, if delay was permissible, by the administration of iron and acids, and metabolism improved by a suitable food supply, while specific or constitutional affections should receive just consideration.

Dr. A. C. STOKES of Omaha said there was referred to him an anemic, pale woman, fifty-six years of age, in whom beginning carcinoma of the rectum was suspected. She was given an anesthetic for the purpose of examination. A speculum was introduced well up into the rectum without producing any great amount of traumatism to the mucous membrane. After this the patient was returned to bed and kept there on account of her anemic condition. Four days later she developed phlebitis. He was unable to say whether the phlebitis was due to the traumatism of the rectum or to the anesthetic. He thought it was the anesthesia, which produced a general toxemia in some cases, and this might produce in turn a chemical change in the blood, which at times might produce, in connection with rest in bed, venous stasis, etc. He was inclined to believe that the great majority of these cases were septic, and whenever he saw a case of phlebitis he always searched for a focus of infection.

Dr. HARRY M. SHERMAN of San Francisco cited one case from his own practice of phlebitis of the left femoral vein, and mentioned two others occurring in the practice of other surgeons, all three operations having been done by different men, and each operation being different.

Dr. LEONARD FREEMAN of Denver pointed out that femoral phlebitis occurred in connection with appendicitis, even when no operation was done. He had seen a double femoral phlebitis occurring in a case of appendicitis within a few days, with the patient not lying in bed. Phlebitis occurred in connection with other things, when there was no question about septic infection. For instance, in an ordinary Pott's fracture of the right leg, and in one case of simple fracture, left femoral phlebitis resulted in the course of a week or two. In another case of fracture of the left patella a right femoral phlebitis developed, and a left phlebitis afterward. These could not be explained by infection.

Dr. E. S. WRIGHT of Salt Lake City recalled his first case of phlebitis, following an operation for appendicitis. The appendix had ruptured and had filled the pelvis with pus. He drained through the cul-de-sac, and the vagina had become partially obliterated. Possibly the traumatism incident to the introduction of the speculum in this case contributed to the result. The patient recovered from the phlebitis without any particular treatment.

Dr. J. CLARK STEWART of Minneapolis said the general impression among pathologists was that thrombosis was in many instances of bacterial origin. The term sepsis was the *bête noir* of the surgeon, and naturally surgeons refused to accept sepsis as a cause of anything in connection with what they were doing. If the term bacteriemia was used, they would be perhaps more willing to accept it. It would seem that many cases, if not all, of thrombosis were due to bacteriemia. Pus bacteria entered the blood from sources unknown, and gave rise to such diseases as osteomyelitis. We knew nothing of the way the various bacteria got into the blood, but we knew in a great many cases there

was a distinct bacteriemia. There was only one way to do, and that was to have blood cultures made in cases of femoral thrombosis. Bacteria in the blood did not necessarily mean sepsis in a surgical sense, as a patient might have a certain number of bacteria circulating in the blood without clinical manifestations. It was only when some point of least resistance occurred that the lesions were localized.

Dr. Andrew C. Smith of Portland, Ore., recalled three cases of phlebitis in three different types of operations in his own work. None of them was immediately septic, but each of them was remotely septic. He attributed each case to the catgut, and thought the slight sepsis due to late disintegration of the chromic catgut, and the absorptions of toxins from that.

Dr. Union Worthington of Salt Lake City did not believe that trauma was a cause of phlebitis. Whenever he had a case of phlebitis it was his practice to look for infection, just as it had been his practice to look for a focus of pus when he saw a case of rheumatism. The fact that phlebitis more frequently occurred in the left leg than in the right had never been satisfactorily explained to him.

Dr. Grant, in closing, expressed the belief that blood examinations by bacteriologists and pathologists would have to settle the question. Pathologists had not been given a good chance thus far, because most of the patients recovered; but the rather dogmatic statement of Murphy that recumbency was the cause could not be accepted. It might be one of several causal factors.

The Principles and Mechanics of Abdominal Drainage.—Dr. R. C. Coffey of Portland, Ore., read a paper on this subject, in which he presented the following deductions: "1. Fluids are rapidly absorbed by the peritoneal cavity; crude or granular matter only through lymph spaces at the diaphragm. 2. A drainage tract always contains microorganisms. 3. Any form of drainage is isolated from the free peritoneal cavity in six hours. 4. A drain causes a flow of serum by irritation, which is profuse in proportion to the amount of drain within the peritoneal cavity. 5. This flow is delivered to the surface only in proportion to the amount of drainage passing out through the wound. 6. Serum and pus accumulate around drainage only when the drainage at the outlet is less than that contained inside, or is not sufficiently extensive to deliver the fluid before it is filled with débris and granulations. 7. Blood and pus are never found in the neighborhood of a properly applied drain after forty-eight hours. 8. The flow of serum dissolves blood clots and thick pus, leaving the gauze clean and white by the time it ceases. 9. The flow of serum does not occur to any extent in formed abscess cavities; therefore, blood and pus are not well drained from them by capillary drainage. 10. A tube will drain a walled cavity and will drain the peritoneal cavity under the influence of gravity, but not otherwise. 11. A single tube is much more likely to be choked by intestines and omentum than two or more parallel tubes. 12. Gauze drains in proportion to the amount coming through the opening, and will only drain when it is in contact with dressings or clothing, or when its outside end is at a lower level than the cavity to be drained. 13. Small gauze drains are likely to be choked at the exit, unless covered by a tube or protective. 14. There are three cavities of the peritoneum to be drained, the right and left flank, separated from each other by the spinal column, and the pelvis, separated from the flanks by the psoas muscles. Either flank holds more fluid, and is an inch deeper than the pelvis, and its bottom is more than four inches below the top of the divide made by the psoas muscle, on which the appendix rests. The body must be elevated to an angle of 51 degrees, to bring the bottom of the flank on a level with the divide, and 60 or 70 degrees to properly drain by the Fowler position. The entire cavity can be drained by gravity by a lateral position. 15. Drainage should always be in contact with the parietal peritoneum on one side. A line drawn from the center of the perineum to the tip of the shoulder passes through the pelvis and deepest part of the flank, and on the right side through the appendix. These diagonal lines we call the right and left drainage lines. Drainage should always be placed external to these lines or just above the pubic bone. 16. If only one of the three cavities is infected, it alone should be drained." His conclusions were: "Drainage must be extensive enough to do its work in less than six hours, and should reach the bottom of every infected cavity, either by gravity or drains. It should not be removed until it is loosened, which varies from six to fourteen days. Given the principles and mechanics of drainage, and a competent surgeon is able to fit his method to the case. Peritoneal drainage, intelligently used, is one of the most effective life-saving agents at our disposal."

Intestinal Suture.—Dr. A. F. Jonas of Omaha described and demonstrated a modified intestinal suture.

Complications, Accidents, and Sequelæ Incident to Prostatectomy.—Dr. J. N. Warren of Sioux City, Iowa, spoke of the condition of the gland influencing operation, and also of the presence of active or chronic infection. He referred to the condition of the bladder as to contraction or dilatation as a complication; also the presence of vesical calculi, accidents, hemorrhage, puncture of the bladder, rectovesical fistula, rectal fistula, and methods of management, sequelæ, incontinence or retention necessitating resumption of catheter, impotence, etc.

Dr. George Goodfellow of San Francisco said that up to the present time he had made 105 operations for the removal of prostates, with two deaths. He gave a full explanation of the cause of this low mortality.

Dr. Grant asked as to the proportion of cases suffering from incontinence.

Dr. Goodfellow replied that he had had no case of total incontinence. He had had up to the present time four cases of partial incontinence, in which the patient was able to retain from four to six ounces of urine for a short time. The cases of total incontinence usually never lasted over four months. In one case a fistula lasted eleven months.

Dr. Charles H. Mayo of Rochester, Minn., said that prostatectomy was not a minor operation. It had a fixed mortality that any type of serious operation would involve. He believed that the mortality from this operation was about 6 per cent. Dr. Goodfellow, an expert in this line of work, had a better mortality rate than most surgeons.

Massage of the Heart in Apparent Death from Anesthetics.—Dr. D. S. Fairchild of Des Moines, Iowa, reported a case of massage of the heart in apparent death from anesthesia, and reviewed the literature of twenty-four other reported cases. He spoke of the time after arrest of the heart when positive results might be expected. He discussed the best route for approaching the heart for the purpose of massage.

Peripheral versus Intracranial Operations for Tic Douloureux.—Dr. Charles H. Mayo of Rochester, Minn., said that more methods of internal, external, and surgical treatment had been advanced for the cure of facial neuralgia than for any other condition. In 1896 Dr. Abbe reported a case in which he interposed mechanical obstruction to the reunion of the nerve, by placing rubber tissue over the foramina of exit of the nerves in the skull. For nine years Dr. Mayo had employed silver screws to obstruct the infra-orbital foramen after torsion and removal of the nerve by the Thiersch method. For a shorter period the inferior dental canal had been obstructed, with equal success. While not as effectual as the intracranial operation, because of the numerous branches, still the method controlled the two branches most commonly affected. It could be employed on many who would not submit to an intracranial operation, with its attendant mortality and occasional failures to cure.

Aneurysmal Varix.—Dr. J. Clark Stewart of Minne-

apolis read a paper on this subject, in which he reported an interesting case of large aneurysmal varix of the forearm, and exhibited photographs. He presented histories of such cases, and described the operative methods used. He likewise discussed the proper treatment of the lesions in the upper and lower extremities, and considered the radical difference in the conditions present.

Sarcoma of the Male Breast.—Dr. F. GREGORY CONNELL of Salida, Col., reported this case. The patient was twenty-five years of age. The mother had both breasts removed for cancer. There was no history of traumatism. The tumor started in a congenital discoloration of the skin near the right nipple, and in three months had grown to the size of a walnut. The breast and axillary glands were removed. The healing of the wound was perfect. Two months after discharge the patient presented himself for examination, and a keloid was found to have developed in the cicatrix. When last seen, six months later, the keloid was smaller, and there was no evidence of a recurrence of the sarcoma. Histological examination showed the tumor to be a spindle-celled sarcoma. The author made some remarks upon the frequency of this condition in the male, and reviewed the literature.

Malignant Complications and Degenerations of Uterine Fibromyomata.—Dr. CHARLES W. OVIATT of Oshkosh, Wis., in a paper on this subject, said the conclusions which were forced upon him by a study of reported cases were: "(1) Women suffering from fibroid disease of the uterus incur a greater risk in allowing it to remain than in having it removed by a competent surgeon. (2) The fact that adenocarcinoma of the body of the uterus occurs much more frequently in cases of fibroid tumor than does cancer of the cervix gives rise to the belief that there must be a direct causative relation between fibroid tumors and cancer of the body of the uterus. (3) Every fibroid tumor removed should be subjected to careful laboratory study, no matter what its gross appearance."

Treatment of Tuberculosis of the Kidney and Bladder by Nephrectomy.—Dr. LEONARD FREEMAN of Denver, Col., after detailing fourteen cases upon which he had operated for tuberculosis of the kidney and bladder, drew the following conclusions: "(1) Tuberculosis of the urinary tract very often begins in the kidney, attacking the bladder secondarily. (2) It is usually at first unilateral. (3) Medical or climatic treatment is unsatisfactory in most cases. (4) The ideal treatment is early nephrectomy, providing there is one sound kidney. (5) Tuberculosis elsewhere, unless far advanced, is not a contraindication to operation. (6) Tuberculosis of the bladder derived from one kidney is positively benefited by nephrectomy, and can seldom be cured without it. (7) The demonstration of tubercle bacilli in the urine often fails. (8) The removal of the ureter is not ordinarily indicated. If sinuses result, they nearly always heal with time."

Injuries of the Ureter.—Dr. A. H. KERR of Salt Lake City read a paper on this subject, in which he reported a case of ureteral cystostomy or ureterovesical implantation.

Operative Procedures for Chronic Urethritis.—Dr. A. C. STOKES of Omaha discussed incurable gonorrhea in the male. He gave the reasons why this disease is so often not cured, and spoke of the havoc worked by gonorrhea in civilized communities. A minute anatomical and pathological diagnosis must be aimed at, and having once arrived at a definite diagnosis as to the position of the infection, one should resort to the methods that are most applicable to its treatment. He spoke of external urethrotomy in its relation to chronic gonorrhea, and of operations for vesiculitis, prostatitis, and old infections of the vas deferens. He reported four cases in which chronic gleet was treated by external urethrotomy and cauterization of the prostatic follicles and urethra. He discussed vasotomy in the treatment of infections of the seminal vesicles and epididymis. He described the technique of the latter procedure, and reported five cases in which he had operated.

Papers were also read by the following members: "The Control or Elimination of Pneumothorax During Operations on the Chest," by Dr. Dudley Tait of San Francisco; "Abdominal Contusions," by Dr. Wm. Jepson of Sioux City, Iowa; "A Point in the Technique of Ligating the Appendix in Appendectomy," by Dr. Jabez N. Jackson of Kansas City, Mo.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Chas. W. Oviatt of Oshkosh, Wis.; *First Vice-President*, Dr. S. C. Baldwin, of Salt Lake City; *Second Vice-President*, Dr. Jabez N. Jackson, of Kansas City, Mo.; *Secretary-Treasurer*, Dr. Arthur T. Mann of Minneapolis.

St. Louis, Mo., was selected as the place for holding the next annual meeting, in the latter part of December, 1907.

AMERICAN PEDIATRIC SOCIETY.

Eighteenth Annual Meeting, Held at Atlantic City, N. J., May 30, 31, and June 1, 1906.

THE PRESIDENT, DR. A. JACOBI, OF NEW YORK, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

First Day—Wednesday, May 30.

Suggestions as to the Classification of Gastroenteric Diseases on an Etiological Basis.—Drs. THOMAS MORGAN ROTCH, MAYNARD LADD, and CHARLES H. DUNN of Boston presented this communication. The following classification had been adopted by the department of Pediatrics of Harvard University. Objections to former classifications were that they were on several different bases, and there were many difficulties in the way of classification on an anatomic and on a symptomatic basis. Recent progress showed a distinct tendency toward the adoption of the etiological basis.

GASTRIC.

Developmental	Malpositions	
	Malformations—	Pyloric Stenosis
Noninfectious	Mechanical	Contraction
		Dilatation
	Ulcers—	Peptic
	New Growths	
	Functional	Nervous Vomiting
		Recurrent Vomiting
		Indigestion
	Traumatic	Corrosive Gastritis
Infectious	Gastritis	

ENTERIC.

Developmental	Malpositions		
	Malformations		
Noninfectious	Mechanical		
		Dilatation of Colon	
		Volvulus	
		Intussusception	
		Hernia	
		Fissure	
		Prolapse	
		Hemorrhoids	
	New Growths		
	Functional		
		Nervous Diarrhea	
		Indigestion	
		Duodenal	Deficient Secretion
		Intestinal	Fermentation
		Incontinence	
		Constipation	

Infections

Infectious Diarrhea { Dysentery / Cholera Infantum / From Other Organisms.

Proctitis

Appendicitis

Fistulæ

Intestinal Worms.

Dr. L. Emmett Holt of New York thought that all were coming in the end to classification on an etiological basis. Yet there were some points on which there was a difference of opinion; yet, in the main, he favored the scheme. It was a definite addition to the ideas on the subjects.

Dr. B. K. Rachford of Cincinnati asked why enteritis was dropped in the classification.

Dr. A. Jacobi of New York asked if, under enteric diseases, ulcers had been left out on purpose.

Dr. J. P. Crozer Griffith of Philadelphia believed this to be a great improvement upon past classifications.

Dr. Rowland G. Freeman of New York thought it might be advantageous to divide the classification on an anatomical basis, as seen at autospy.

Dr. Thomas Morgan Rotch wished it to be understood that the classification presented was a PRIMARY one, and subdivisions might be added after further study

Some Phases of the Feeding Problem.—Dr. L. Emmett Holt read this paper, and asked for greater simplicity and flexibility in infant feeding. Healthy children should not have a proportion of fat above four per cent., and sometimes even three per cent. was excessive, and very often one per cent. was the limit. More failures in modified milk occurred because of the avoidance of the proper proportion of fat than from anything else. Reason was a lack of knowledge of the child's normal capacity of digestion. Dr. Holt's method was to multiply the percentage of fat in the milk by the number of ounces of milk in the formula, and divide this by the number of ounces called for in the formula. He asked for a method for remedying the evil, although his hopes were centered upon the students of medicine, who should be properly taught the normal range of milk percentages, as well as the approximate percentages of ingredients of the whole milk, the top milk and the cream; they should also be taught the simplest possible method of obtaining the percentages desired.

Acidified Milk in Infant Feeding.—Drs. John Lovett Morse and Henry J. Bowditch of Boston presented this paper. They told of the souring of milk by lactic acid forming organisms. Buttermilk consisted of cream, etc., with casein, in finely divided form, and with large proportion of albumin. This should not be used, except when other foods could not be digested. Stools always were found to be alkaline in reaction. Buttermilk had a large fat content, and was usually used with the addition of sugar flour, and had always been taken willingly. Buttermilk was particularly valuable in cases of chronic indigestion, and after the starvation period of acute diarrheas. The question arose whether the good resulted from the acidity, from the presence of bacteria, or from both. Reports of cases followed. He concluded that milk acidified with bacterial living organisms did well, even in young infants. The addition of cream to buttermilk added to its caloric value. Practically all the babies did well on pasteurized buttermilk, and this food could be used whether children were well or ill. Possibly unpasteurized buttermilk would give better results than the Pasteurized.

Dr. Graham of Philadelphia asked how long babies were kept on the buttermilk

Dr Thomas S. Southworth of New York referred to the form in which casein existed in buttermilk, and said the different types should be more studied. The lactate of casein should be more readily digested than the tough curds so often encountered.

Dr. I. A. Abt of Chicago asked whether in the absence of fat, the carbohydrates, in the form of starches and sugars, could make up for its loss.

Dr. John Lovett Morse of Boston, in answer to Dr. Graham's question, said that babies with acute diarrhea had been kept on buttermilk from three days to two weeks Dr. Abt's question he could not answer.

Observations Concerning the Nature of Atrophy of Intestinal Origin.—Dr. D. L. Edsall of Philadelphia reported some results of observations made, yet incomplete. Further studies were to be made and reported.

Dr. L. A. La Fètra of New York and Dr. A. H. Wentworth of Boston, discussed these observations.

Modified Wet Nursing.—Dr. Thompson S. Westcott of Philadelphia read this paper. He spoke of the great difficulties attending the endeavor to secure a suitable wet nurse, even at any price. His paper dwelt more with those cases in which the infant's life was at stake. The method consisted in the giving of human milk in combination with some artificial food. Sometimes two or three women would contribute in this life-saving of the infants. Dr. Wescott related the history of a case, illustrating the value of this method of infant-feeding.

Dr. A. C. Cotton of Chicago called attention to the revivifying influence of even a few drops of mother's milk upon the baby. He said that more should be taught regarding the value of mother's milk than to percentages. He thought that every local pediatric society should take up this matter and form a bureau or registration for wet nurses, under a competent committee appointed by the local society.

The Relationship of Weight and Length in Infancy.—Dr. Rowland G. Freeman showed a number of charts, showing the comparative curves of weight and measurements of 500 institutional children, divided into well-nourished, fairly-nourished and poorly-nourished children. During the first year of life the primary factor in increasing the body was the increase in weight. The influence of age was of very much less importance.

Weight in the First Two Weeks of Life.—Drs. J. P. Crozier Griffith and J. Clayton Gittings of Philadelphia presented this communication which considered the birth weight and the causes influencing it. Also the loss and gain in weight during two weeks of life, and the factors influencing it. They asked whether the initial loss was *physiological*. They weighed 226 infants, with an average initial weight of 7 lb. 9.9 oz. There were 111 males and 115 females. There was an average difference of 3 oz. between male and female initial weights. By comparison, fair average birth weight might be considered as males averaging 7 lb. 8 oz., females averaging 7 lb. 3 oz., an average difference between the sexes of 5 oz. The initial weight might vary considerably, and infants weighing from 6 to 9 lbs. might be considered normal. Apart from the influence of the sex of the child, a number of other factors must be considered as affecting birth weight. These figures did not show the steady increase of Fleischmann, yet Duncan's statement was confirmed by them that the largest weight fell between twenty-fifth and twenty-ninth years. Their observations on 226 cases gave an average weight of children of primiparæ equaling 6 lbs. 14.37 oz., and of multiparæ 7 lbs. 10.72 oz. They concluded that increase in weight was to be expected in the children of multiparous as compared with primiparous woman. The increase would vary from 2 to 12 oz. In their own observations upon alterations in weight, 165 full-term children were studied. From a study of their results, it was apparent that the "ill" cases suffered a loss only slightly greater than the healthy cases, but the time of the initial loss was prolonged and the day of regain was later. In general, they concluded that in the majority of the cases the minimum weight was reached by the third or fourth day, and the initial weight was regained by the tenth to the fourteenth day. Haake believed the initial loss in weight was physiological. This was to be looked upon as one of the links in the chain of physiological changes in the new-born.

Dr. L. Emmett Holt of New York said figures of his own corresponded with those of Dr. Freeman.

Dr. Henry Koplik of New York criticised the custom of most practitioners of force-feeding the baby during first days of life. There was much traumatism produced by placing a baby at breast every two hours during first twenty-four hours.

Dr. F. S. Churchill of Chicago said he had noticed that in breast-fed babies the rate of gain was very apt to fall off about the sixth or seventh month.

Dr. Thomas Morgan Rotch said that some significance should be attached to the fact that in the third quarter the stomach did not grow so rapidly as during the first and second quarter.

Dr. A. Jacobi of New York emphasized the importance of giving these babies plenty of water to supply the amount lost during first few days.

Dr. Henry D. Chapin of New York also discussed the papers. Discussion was closed by the readers of the papers.

Primary Tuberculous Infection of the Intestine in a Nursing Baby, with Specimen.—Dr. Irving M. Snow of Buffalo reported this case, and presented the specimen. The patient died of intestinal hemorrhage. The autopsy showed interesting findings in stomach and intestines. Eight inches from the ileocecal valve was a mass of lymph nodes. There was ulceration of the intestine, and above that point the gut was filled with blood. There was also ulceration of the stomach. The colon contained blood. Sections of pustules on the skin revealed the presence of the tubercle bacilli. The source of infection was through the nurse. Some had claimed that the tubercle bacilli could pass through the intestinal mucosa without leaving any trace whatever.

Dr. B. K. Rachford of Cincinnati reported the case of a child born of a woman far advanced in tuberculosis. This child was wet-nursed and placed in the best hygienic surroundings, and now, twelve years of age, was in splendid health and without a symptom of tuberculosis.

Dr. Wm. P. Northrup of New York related a case directly opposite to the one related by Dr. Rachford, the baby, at the age of six weeks, dying with cavities in both lungs.

Dr. Rachford asked if it was true that there was a primary tuberculosis of the intestinal mucosa and a secondary tuberculosis of mesenteric nodes.

Dr. Samuel S. Adams of Washington said that, in his experience, in the majority of the cases the mesenteric glands were found to be tuberculous, with but little lesion of the mucosa.

Dr. Thompson S. Westcott of Philadelphia reported the instance of a child dying at the fourth month that exhibited tuberculosis of the lungs apparently secondary to extensive involvement of the bronchial glands at the root of the lung, one of which was very large and cheesy.

Dr. L. Emmett Holt of New York was particularly interested in tuberculous lesions of the skin. He believed many cases had been overlooked because we looked for milk infection to the exclusion of other sources of infection.

Dr. S. McC. Hamill of Philadelphia and Dr. Alfred Hand, Jr., of Philadelphia, discussed the paper. The discussion was closed by Dr. Snow.

Tuberculous Cervical Adenitis in a Four Months' Infant.—Dr. L. E. La Fétra of New York made this report, because of its rarity, and because of certain interesting questions that arose in connection with it. The family history threw no light upon the origin of the affection. The child was born at full term, was strong and healthy, was nourished by a combination of maternal nursing and bottle feeding, the milk being produced under the best conditions. When three weeks old he developed a cold in the head, which soon passed off. When seven weeks old he developed a second cold. The tonsils, especially the right, showed a little exudate, but with little redness or swelling. Under treatment the condition improved. A third attack of cold followed, which lasted thirteen days. When ten weeks of age a slight swelling appeared on the right side of the neck, consisting of three lymph nodes, which remained the same size for about ten days, then increased rapidly for a few days, but without any rise of temperature above 100.5° F. Soon the swelling was the size of a walnut, and quite hard, and the node outlines became lost. Then the swelling diminished, and the three nodes were again distinctly felt, firm, not tender and movable. Again the swelling began, and the outlines of the separate nodes were lost, and there was indistinct fluctuation in the tense lobulated mass. Dr. Chas. N. Dowd was called in consultation, and, upon his advice, the neck swelling was operated upon. The lymph nodes were found to be quite large, soft and hyperplastic, but there was no suppuration. When opened the nodes showed grayish granular material, but no distinct pockets of liquefaction. There was very little fibrous tissue about the lymph nodes. The microscopical examination showed extensive early tuberculosis. There were many areas of degeneration and necrosis in the lobules of the nodes. These areas were surrounded by a slight amount of productive inflammation.

Dr. Henry Koplik of New York did not believe the tonsils to be the source of infection in so many cases of infection of the cervical lymph nodes, as was so generally supposed.

Dr. A. C. Cotton of Chicago and Dr. Hess of Chicago discussed the paper.

A Case of Tuberculous Pericarditis, with Frequent Aspiration of Fluid from the Pericardial Sac. Death from Tuberculous Meningitis.—Dr. Alfred Hand, Jr., of Philadelphia, reported the case of a boy, 8 years old. From the history of the case and examination of the aspirated fluid, a diagnosis of pleuroperitoneal tuberculosis was made. Symptoms of tuberculous meningitis appeared, and the patient died soon after. The findings of an imperfectly recorded autopsy were reported.

Dr. J. P. Crozer Griffith of Philadelphia sympathized with the difficulties in making the diagnosis of tuberculous pericarditis.

Dr. I. A. Abt of Chicago spoke of the dangers of doing pericardial aspirations. In one case death followed cutting through both parietal and visceral pericardium, which were adherent.

Dr. Henry Koplik of New York said that pericardial aspirations were dangerous in infants and children, this danger being increased by the sacculation which occurs so often in young subjects.

Dr. Thomas Morgan Rotch of Boston said that a dilated heart did not extend much to the right of the sternum when at or below the fifth intercostal space. When effusions were present they would occupy the same area, so far as percussion showed.

Dr. John Lovett Morse of Boston said that one should not aspirate unless he felt that it was necessary.

Dr. D. L. Edsall of Philadelphia called attention to the differential point of throwing the patient forward on the front of the chest, to determine the influence of this position upon the compression signs at back of chest.

Dr. Alfred Hand, Jr., closed the discussion.

The Teaching of Scientific Infant-Feeding. A Plea for More Uniformity.—Dr. Henry D. Chapin of New York read this paper. He said that many years' experience in teaching the subject of artificial infant feeding to post-graduate students had shown that the subject was not as clear to them as it might be, and that they did not look upon it as being established on a firm, scientific basis, and it could not progress uopn such a basis until some principle were etablished beyond dispute. One of the first things to be settled was a uniform nomenclature, so that terms should be used in a restricted and definite manner. Much of the work done on infant feeding had less value than it ought to have from the amount of work expended, because it was uncertain just what many terms were intended to cover. For instance, in the earlier analyses of milk all of

the nitrogenous bodies were called casein, then they were called albumin, albuminoids, and proteids. Later the word casein was applied to the curd-forming portion of the proteids. It was not at all unusual to find these terms used indiscriminately in modern text-books. The introduction of the term caseinogen had increased the confusion. Dr. Chapin said it would be more scientific to state what form of casein was being fed, as follows: Simple diluted milk, normal calcium casein; milk and lime water, basic calcium casein; milk and bicarbonate of sodium, basic calcium casein and antacid; milk and citrate of sodium, sodium casein; buttermilk, casein lactate. From what he said, it was apparent that when foods having such different properties were used, it was important to report more than their percentage composition, as their behaviors in the stomach were so unlike.

The "23 Cure."—Dr. Wm. P. Northrup of New York read this paper, which dealt with living twenty-three hours out of the twenty-four in the open, fresh, flowing air. This was especially beneficial in cases of convalescence from acute illness and in cases of delicate children. The quality of the cold or cooled fresh air was essential. The cold, fresh, flowing air uniformly had certain effects upon young children. They slept better, took and assimilated more food, and rarely did they catch cold. At See Breeze, Coney Island, no child had ever contracted pneumonia because of living so long in the open, cool, fresh, flowing sea air.

Second Day—Thursday, May 31

The President's Address.—Dr. A. Jacobi of New York, himself serving a second term as President, thought that a second term should not be allowed. He considered cases of membranous throat diseases, and stated that they behaved differently, according to the location of the membrane. For instance, if limited to the tonsils, there would be but little glandular swelling in the neighborhood. If this extended beyond the tonsil, or started away from the tonsil, the neighboring lymph bodies became involved. In uncomplicated cases of laryngeal diphtheria there practically was no glandular swelling or fever. This latter fact had been known for thirty years. An explanation of this amount of involvement was to be found in the consideration of the anatomy of the parts; this Dr. Jacobi considered. It was formerly concluded that no germ or toxin could gain entrance to the circulation unless there was a break in the walls; a surface lesion must be supposed to exist if living germs or toxins were to gain entrance. In conclusion Dr. Jacobi offered certain facts in connection with the absorbing and transmitting power of the tonsil. The surface epithelium of the tonsil was not uniform, and might admit foreign material without any lesion. Thus invasion without lesion was possible.

Anemia Infantum, Pseudoleukemia of von Jaksch.—Dr. Henry Koplik of New York read this paper. He considered the three theories of the condition. He reported nine cases, covering a period of five years' observation, all being hospital cases and subjected to close study and examination. Three of the nine cases terminated fatally. He called attention particularly to the instability of the blood pictures, even when under observation without variations in the clinical symptoms. There was no definite pathological picture, but a severe anemia in subjects in whom there were disturbances of the function of the blood-forming organs, causing a retrograde to the fetal condition. The clinical features were characteristic. There was nothing specific in post-mortem findings, nothing to distinguish it from any other severe anemia. There was nothing either to suggest leukemia except enlarged liver and spleen. These cases fall easy victims to tuberculosis and pneumonia.

Dr. John Lovett Morse of Boston said the symptom complex was that of von Jaksch's anemia. He did not believe this should be separated out and given a special name in the class of severe anemias.

Dr. S. McC. Hamill of Philadelphia reported the case of a colored child, who gave the clinical picture of von Jaksch's disease. The child had been anemic for a number of months. The only symptom, not commonly associated with von Jaksch's disease, was the persistent elevation of temperature. The child died of a pneumonia, and at autopsy there was found a marked enlargement of the spleen, which was the seat of a miliary tuberculosis; the spleen was simply riddled. He wondered if the case was primarily one of von Jaksch's disease.

Sepsis in the Newly-Born, with Post-Mortem Reports.—Dr. A. C. Cotton made a very full and detailed report, particularly of the post-mortem findings, macroscopical, microscopical, and bacteriological, of two cases.

Dr. S. McC. Hamill of Philadelphia said that he had already reported twelve such cases to the society, and then reported another case.

Dr. D. L. Edsall of Philadelphia wished to emphasize the value of blood cultures in those instances in childhood where the diagnosis was difficult, reporting a case to show his contentions.

Dr. Thomas Morgan Rotch of Boston told of the value of blood cultures and of the difficulty in getting the blood in infants.

Dr. Henry Koplik of New York referred to the patches found in the mouths of newly-born infants, and quoted Ebstein's theory as to their formation.

A Case of Septic Endocarditis.—Dr. B. K. Rachford of Cincinnati reported the case of a boy, four years old, who entered the hospital with scarlet fever. One week later endocarditis developed, which was not associated with cardiac distress. He was in the hospital sixty-eight days, and was discharged in good condition. Five days later he was taken ill with ulcerative tonsillitis. This was followed by a septicopyemia. The symptoms gradually subsided, and the child improved in health and strength. He next contracted measles, which aggravated the endocarditis. A bronchopneumonia developed, and then a cancrum oris, and he died 139 days after the onset of the scarlet fever.

A Case of Septic Endocarditis Following Suppurative Otitis Media.—Dr. Alfred Hand, Jr., of Philadelphia, reported the case of a girl, eleven years old, with hereditary syphilis, who had rheumatism when nine years old and measles when ten years old. There was a sudden onset of attack, with fever, dizziness and great thirst. Before admission she was in stupor. On admission the temperature was 103.2° F., and at death, forty-eight hours later, it was 108.4° F. Autopsy findings were reported.

Dr. Thomas Morgan Rotch of Boston said the various forms of endocarditis would be divided on an etiological basis, as septic, rheumatic, from influenza bacillus, etc.

Dr. Henry Koplik of New York reported a case of septic endocarditis, in which there was no history of rheumatism or murmur over the heart. Rheumatism may develop with a septic form and *vice versa*.

Dr. D. L. Edsall of Philadelphia reported a case similar to Dr. Hand's case, in which blood culture proved of great diagnostic value.

Dr. John Lovett Morse of Boston said that few physicians in private practice realized how often a general infection of the ear, with thrombosis of the lateral sinus, caused disease of the endocardium.

Dr. Leroy M. Yale of New York and Dr. F. S. Churchill of Chicago discussed the paper. Discussion was closed by Dr. Hand.

Inorganic Late Systolic Murmurs in Infancy and Childhood.—Drs. S. McC. Hamill and Theodore Le Boutillier of Philadelphia presented this paper. From descriptions in the literature, they said they felt justified in assuming that all murmurs described as functional, inorganic, or anemic, being systolic in time, and having their point of maximum intensity in the pulmonary area, were identical with the murmur which they were to discuss. This murmur did not occur with the first sound; the first sound was always distinctly audible, and the murmur was superadded.

sometimes with a definite interval of silence, especially when it was not loud, and was mesosystolic in time. This was one of the principal characteristics of the murmur. It was ordinarily soft blowing in character, moderately high-pitched, occasionally almost musical, and more rarely low-pitched and rough. It varied in length and in duration. Its point of maximum intensity was most often the second left interspace close to the sternal border. The position of the patient, the respiratory act, and exercise, had a striking influence upon this murmur. It was always greatly increased in the recumbent posture. It was best heard at the end of expiration, and was exaggerated by exercise. The character of the second pulmonic sound in their experience had been invariably accentuated. Ordinarily, the murmur was not transmitted over a very wide area. The position of the apex beat was not altered, and the area of heart dullness was not increased. In the series of eighty cases reported, there were but a very few instances of a marked degree of anemia, and in one case, in which the murmur was present, the hemoglobin content was 100. They were unable to offer any new theory as to the cause of the murmurs. Adding together the number of cases examined consecutively in the preparation of a former paper, and forty-six cases examined consecutively in the preparation of this paper, there was a total of eighty cases, of which fifty-three, or 66.2 per cent., showed the murmur. Of these eighty cases, forty-eight were under five years of age, and of this number thirty-two, or 66.2 per cent. had the murmur. Of the thirty-two remaining, all of whom were over five years of age, there were twenty-one, or 65.3 per cent., with the murmur. On the basis of these figures, therefore, it would seem that in institutional children, showing no special manifestations of disease, acute or chronic, but influenced by their environment, between 60 and 70 per cent. had the type of murmur under discussion, and that this murmur was quite as common in children under five years of age as in later childhood.

Dr. Wm. P. Northrup of New York referred to the work done at Infants' and Foundling Hospital, and said that in fourteen or fifteen years only one case was found of ulcerative septic endocarditis, although many murmurs as described by Dr. Hamill, but in no case could a lesion be discovered.

Dr. Henry Dwight Chapin of New York said he was often confused by hearing murmurs, particularly at the base of the heart, which he could not account for. Not infrequently they disappeared. He felt sure that in children we had murmurs, and they were more common, but not organic.

Dr. D. L. Edsall of Philadelphia said he often heard this murmur when there was no disturbance of health. He also noted it in cases of typhoid fever. Pressure of the conus arteriosus against the chest may produce murmur, a point Dr. Thayer and Dr. McCallom had called attention to.

Dr. L. E. La Fètra of New York was impressed with presence of this murmur in all kinds of fever, and he had called it a "functional fever murmur."

Dr. L. Emmett Holt of New York said that with marked degrees of anemia murmurs were present. He called attention to difficulties of diagnosis of functional murmurs from congenital murmurs when unaccompanied by cyanosis.

Drs. I. A. Abt of Chicago, John Lovett Morse of Boston, D. L. Edsall of Philadelphia, and Thomas Morgan Rotch of Boston discussed the paper. Dr. Hamill closed the discussion.

Multiple Rhabdomyomata of the Heart Muscle.—Drs. J. H. Knox and E. H. Schorer of Baltimore reported this case, which occurred in a marantic colored infant of seven months of age. She was admitted to the Thomas Wilson sanatorium. The tumors were described as firm, grayish-yellow masses, 3 to 5 inches in diameter infiltrating the myocardium; there were also larger tumors, one about 2 cm. in length, pedunculated, and arising from the apex of the ventricle, and extending almost to the aortic valve. At the base a tumor mass, about 1 cm. in diameter, was present, having the same characteristics. On microscopical examination these tumors were found to consist of spongy material, made up of numerous spaces, many of which contained large, round or polygonal cells, with processes running to the periphery of the spaces. An examination with the higher power of the microscope showed many of these septa about the spaces to be finely striated, and here and there continuous with the muscle cells of the myocardium. In other portions of the tumors these clear spaces were less frequent, and the structure was composed rather of fibers, some parallel, others irregularly striated and continuous with the heart muscle. In these larger fibers crossed striations were very evident. In the literature but few cases similar to the one reported had been found. The explanation of the clear spaces was still uncertain. The authors held the view expressed by Seifert, that the tumors probably arose from proliferation of embryonic cells in the myocardium, and that the clear spaces represented probably retraction of the protoplasm, which formerly may have filled the whole spaces, leaving the striations at the periphery such as were found in the developing embryonic muscle cells. The possibility of the relation of this tumor to Purkinjie's cells, not dissimilar in appearance, and to the cells in the atria ventriculi bundle mentioned by Erlanger in his work upon heart-block, was also referred to.

A Sugar of Milk Graduate.—Dr. Rowland G. Freeman of New York presented this instrument.

The Siphon Aspirator.—Dr. F. Huber of New York presented this. He said the Dieulafoy aspirator was so well known that no detailed description was required. The manner of using it, alternately filling and emptying the glass cylinder, was a familiar story. It was rather a complicated process, one that could be materially simplified. For more than twenty years the writer had employed the following modification. After the chest had been punctured several ounces of the fluid exudate were allowed to flow into the syringe barrel in the usual manner, when the distal stop-cock was opened (the proximal also remaining open), the fluid escaped through this tubing into the receptacle placed on a lower level (chair or floor), as the instrument itself was on the bed it was below the level of the chest. The action was somewhat similar to that of a siphon, the expulsive force or *vis a tergo* being the expulsive power of the pulmonary tissue (the expanding lung filling the space formerly taken up by the serous or seropurulent exudate). This application of the "Dieulafoy" led (after a series of experiments) to the idea of the little instrument he demonstrated. It consisted of two pieces of tubing, appropriate needle, and glass barrel with necessary fittings. An ordinary aspirating or exploring syringe about three and one-half inches in length, holding less than one-half ounce (the lower fitting replaced by a cap provided with two stop-cocks), was employed as a substitute in place of the expensive and elaborate glass cylinder, with the rack and pinion action of the Dieulafoy apparatus. The preferable method of using the apparatus was to fill the tubes and barrel with a sterile salt solution, the distal stop being then closed. The chest was tapped in the usual way, and as soon as the outflow stop was opened, the fluid escaped without any trouble, provided the instrument was on a lower level than the thorax.

Presentation of Some Specimens of Foreign Bodies in the Bronchi and Intestines in Children.—Dr. Thomas Morgan Rotch of Boston presented specimens of foreign bodies in the larynx, bronchi, intestines, etc.

Dr. Wm. P. Northrup of New York spoke of the use of the bronchoscope in the hands of Dr. Emil Mayer, as an aid in removing foreign bodies.

Dr. L. Emmett Holt of New York told of the uselessness of symptoms in locating foreign bodies. He thought surgeons were too willing to operate for foreign bodies in the intestines.

Dr. Henry Koplik of New York referred to the value of

the bronchoscope in extracting a bent pin from a child's bronchus.

Cases of Bromide Eruption.—Dr. L. EMMETT HOLT of New York presented photographs showing the bromide eruption, 170 grains having been taken in ten days. The eruption first showed on the seventh day. Six weeks later it had about disappeared.

A Case of Measles Superimposed on Scarlatina.—Dr. J. P. EATON of Pittsburg reported this case because of its rarity. There was double desquamation and absence of complications.

Koplik's Sign in a Recent Epidemic of Measles.—Dr. J. P. EATON of Pittsburg made this report, having had an opportunity in a recent epidemic. Sixty-eight cases were observed. In thirty-two the discrete spots were recognized from one to three days before the appearance of the rash. In twenty-eight cases the exanthem was present, while in eight cases no exanthem was observed at any time. Drs. HENRY KOPLIK of New York, GRAHAM of Philadelphia, SAMUEL S. ADAMS of Washington, and GEORGE N. ACKER of Washington discussed the first paper, and Dr. ROWLAND G. FREEMAN of New York discussed the second paper.

Area of Impaired Resonance Behind and Beneath the Inner Third of the Left Clavicle.—Drs. S. McC. HAMILL and THEODORE LE BOUTILLIER of Philadelphia presented this paper. This area of impaired resonance was probably due to the posterior position of the lung and the more intimate contact of the chest wall with the great vessels.

Acute Nonsuppurative Encephalitis in Children.—Dr. I. A. ABT of Chicago read this paper and reported two cases. The first child had previously been healthy, but was suddenly taken ill with high fever and unconsciousness, which continued about ten days, when he awakened from his stupor, but was generally paralyzed. The use of one side recovered in a few days, but he now had a right-sided hemiplegia. The intelligence had not suffered to any marked degree. Lumbar puncture was not made, because the father asked that this procedure be omitted. The second case was one called polioencephalitis inferior.

A Case Simulating Peptic Ulcer.—Dr. SAMUEL S. ADAMS of Washington read this paper. The patient was a colored child, eleven years old, who, two hours after a hearty breakfast, complained of severe pain in the stomach, and soon vomited matter described as blood; vomited several times and had severe hiccough. One of the externes made a diagnosis of peptic ulcer from the symptoms. Was given rectal nutritive enemata, and only cracked ice by the mouth. She vomited a brownish red liquid, somewhat frothy. Under treatment she improved. The doubt expressed by the writer as to the diagnosis was borne out by the subsequent history, as it was apparent from the examinations that the vomited blood did not come from the stomach. The conclusion of the writer was that the "vomited blood" was brought from the fauces by a voluntary effort resembling hiccough.

In the evening, a smoker, with the President's compliments, was given, at which Dr. Rowland G. Freeman of New York gave a lantern exhibition, showing "The Influence of Milk Certification on Dairy Hygiene."

Third Day—Friday, June 1.

Election of Officers.—The following officers were elected: *President*, Dr. B. K. Rachford of Cincinnati; *First Vice-President*, Dr. W. L. Carr of New York; *Second Vice-President*, Dr. D. L. Edsall of Philadelphia; *Secretary*, Dr. Samuel S. Adams of Washington; *Treasurer*, Dr. J. Park West of Bellaire, Ohio; *Recorder and Editor*, Dr. L. E. La Fètra of New York; *Member of Council*, Dr. George N. Acker of Washington; *Member of Executive Committee*, Congress of American Physicians and Surgeons, Dr. A. Jacobi of New York; *Alternate*, Dr. W. P. Northrup of New York; *Member of the Committee of Arrangements for the Congress*, Dr. Samuel S. Adams of Washington. The meeting will be held in Washington in May, 1907.

Applications for Membership.—Dr. Frank S. Meara, New York; Dr. John Milton Dodson, Chicago; Dr. R. B. Gilbert, Louisville.

Typhoid Infection Conveyed by a Convalescent Infant.—Dr. THOMAS S. SOUTHWORTH of New York read this paper. He said that the general public and the medical profession were now fairly well informed of the danger from typhoid fever in water, milk, and shellfish, and of the preventive measures to be employed in the disinfection of the excreta of a typhoid patient during the active febrile period of the disease. Recently, however, warnings had been issued that the convalescent might still harbor the bacilli in sufficient numbers to constitute a serious menace to the public health. The circumstances must be exceptional in order to prove such conveyance and to exclude other sources of infection. The author related the histories of two house epidemics of typhoid fever in different cities, the connecting link between which was an infant sixteen months of age, who, preceded and followed by definite cases of typhoid in his own family, passed through an illness with prolonged but relatively moderate temperature, with gastrointestinal symptoms and a complicating pneumonia, without positive Widal at the time, but later giving a positive reaction. This infant after a period of normal temperature for about two weeks, during part of which he was under observation in a hospital, then entered another family and house in which there had been no typhoid fever Three weeks after his arrival there, two children came down simultaneously with the disease, and two weeks later a third child. Painstaking inquiry revealed no other source of infection. The visiting infant was pale and rachitic and had frequent loose stools of foul odor, which required frequent changing of the diapers by a busy woman who had five children to cook and care for. The single faucet of cold water over a sink usually filled with soiled dishes and utensils offered the most available facility for perfunctory hand washing. Every opportunity was offered for infection of the food. Although typhoid bacilli usually had not been found in the stools of convalescents, recent German investigations into the spread of typhoid had established the existence of a considerable number of such persons called "bacillus carriers," in whose stools the typhoid bacilli had been found persisting from three months to ten years after the disease, and to whom cases of "contact infection" had been traced. The infectious character of many urines during convalescence was well established. Typhoid bacilli might be found in the urine in about 21 per cent. of the cases, persisting usually in large numbers and almost pure culture into convalescence; and might be found there for weeks, months, or even for years. The bacilli might be present and persist in the sputum of patients having a complicating bronchitis or pneumonia. There was no sufficiently general recognition of these sources of danger in convalescent patients. With few exceptions they were allowed to go their way without any special precautions. Disinfection of stools and urine ceased with the departure of the trained nurse or discharge from active treatment. Adults and older children passed their stools and urine in the closet when convalescent, but with infants the diaper or vessel was handled and the infant cleaned by some attendant, who might then infect herself or others whose food she prepared. The case related throws light upon some of the apparently sporadic cases. It again directed attention to the mild course at times of typhoid fever in infants and the possibility of not recognizing it if the Widal reaction was delayed, or attention was diverted by complications. No effective methods had been discovered of eliminating the bacilli from the intestinal tract.

Dr. D. L. EDSALL of Philadelphia had failed to find in a

careful inquiry in a large number of cases that the majority of doctors gave their patients any instructions at all, even during the course of the disease, that bear upon contact infection. In having a careful examination made into the records in over 200 cases at the Episcopal Hospital he had found that contact infection was indicated in 17 per cent. of the cases; there was a suggestion of it in 25 per cent.

A Study of Relapses in Typhoid Fever of Children.—Dr. Henry Koplik and Dr. Henry Heiman of New York prepared this paper. The writers said that relapses being as varied as the original attack the treatment was one of difficulty. Prolonged temperature elevation, enlargement of spleen, and roseola were the symptoms to be expected. In 164 cases occurring in the last year there were 24 relapses. Average age, nine years; 13 males, and 11 females. There were 15 per cent. of the total number that relapsed. The tendency to relapse was more pronounced in infant life than in later years. Mortality was exceedingly low in relapsing cases. As a rule temperatures continued high. A constant symptom was enlargement of the spleen, Roseola persisted in 75 per cent. Complications were mild and infrequent.

Dr. Thomas Morgan Rotch of Boston suggested that bacteriological examination of the blood was a reliable adjunct in the diagnosis of a relapse in typhoid fever, as relapses were often difficult to determine.

Dr. I. A. Abt of Chicago said that in many of the cases the spleen remained enlarged from the first appearance of the infection, and at the time of relapse became more enlarged.

A Consideration of Some Possible Etiological Factors in Recurrent Vomiting.—Dr. John Howland and Dr. A. N. Richards of New York presented this paper. They said in part that the etiological factors concerned in the recurrent vomiting of children had always been hidden in obscurity. Most writers had agreed that an underlying neurotic constitution was the cause. Examinations of the urine were made to ascertain the urinary conditions in these cases and the results were tabulated. Additional evidence of faulty oxidation was shown, especially by the increased secretion of sulphur. They thought the belief justified that interference with oxidation was the chief cause. Interference with oxidation was brought about in animals by the injection of various substances such as phenol

Gonorrhea in Infants.—Dr. A. C. Cotton of Chicago reported thirty-one cases, the children being of an average age of three and a half months.

Carbolic Acid Poisoning by Rectal Injections.—Dr. George N. Acker of Washington reported two cases of carbolic acid poisoning. 1. Child aged six years, mother gave rectal injection of carbolic acid, a teaspoonful in a pint of water. Almost immediately noticed the eyes closing; was semiconscious and would not answer. The eyes rolled about. Remained unconscious for nearly three hours and afterward complained of soreness in abdomen. The next day the urine was very dark and had odor of carbolic acid. The injection had been given for seat worms, the father having read in a family medical book that this was the proper treatment for that condition. 2. Child three years of age; family physician had ordered bowel irrigation with boracic acid and mother by mistake had used carbolic acid, teaspoonful to the quart of water. Child became unconscious and remained in that condition with feeble pulse and respiration eight hours. Gradually made complete recovery. For seven days urine had dark color and odor of carbolic acid.

Dr. Samuel S. Adams of Washington recited a case in which carbolic acid had been used in this way for tape worm, and he thought it probable that more of these cases occurred than was generally supposed.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 22, 1906:

	Cases	Death
Tuberculosis Pulmonalis	354	154
Diphtheria	154	16
Measles	55	2
Scarlet Fever	59	2
Smallpox	—	—
Varicella	9	—
Typhoid Fever	134	29
Whooping Cough	30	8
Cerebrospinal Meningitis	5	7
Malarial Fever		
Totals	800	218

Technique of Enterotomy.—Wolf states that he usually, when operating for intestinal obstruction, has a rectal tube placed in position before the laparatomy is begun. In case the obstruction is low down, it is easy after its relief to empty the distended gut through the tube. In case the obstruction is higher up, the following procedure is employed. The lowest possible loop of distended intestine is stripped of its contents and is secured by intestinal clamps; a circular purse-string suture is placed in position and in its center an incision is made sufficiently large to admit a piece of drainage tubing. This is pushed into the intestine a short distance and the suture tightly drawn. In this way the intestine may be emptied without any danger of soiling the peritoneum or the hands of the operator. At the termination of the operation the tube is slowly withdrawn by the assistant, while the suture is tightened by the operator. The spot is then covered over by one or two Lembert sutures.—*Zentralblatt für Chirurgie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ending September 21, 1906:

SMALLPOX, UNITED STATES.

		CASES	DEATHS
Louisiana, New Orleans	Sept 1-8	4	1
Massachusetts, Lawrence	Sept. 1-8	1

THREE URETERS DEMONSTRATED DURING LIFE; URETER-CATHETERIZATION GIVING THREE DIFFERENT URINES, ONE INFECTED WITH GONOCOCCI.

BY BRANSFORD LEWIS, M.D.,

ST. LOUIS.

PROFESSOR OF GENITOURINARY SURGERY, MEDICAL DEPARTMENT OF ST. LOUIS UNIVERSITY.

THIS very remarkable case pertained to a male patient, aged 24 years, referred to me February 3, 1906, by my friend, Dr. J. L. Crook, of Jackson, Tenn.

The history given is one of repeated recurrence, since 1900, of urethral gonorrhea, after unusually comprehensive and intelligent measures for rendering innocuous all possible sources of infection within reach—complete urethrovesical irrigations with approved gonococcocides, given systematically, with and without prostatic and vesicular massage, by Dr Crook, who is versed in such methods, and also by an Eastern consultant, whose opinion had been sought after the case had proved its rebelliousness; yet no lasting success was achieved. The passing of each month found the patient with a reawakened attack of urethral discharge which was repeatedly proved to contain abundant gonococci, and by several investigators, aside from those named.

At first I went through a similar experience: I applied my attention to the disinfection and treatment of the lower urinary tract for about two weeks, without making any definite headway, when I determined to learn what light could be thrown on it by ureter

FIG. 1.

catheterization. In making numerous examinations for gonococci, my assistants had noted one peculiarity about them: usually the organisms were not so numerous in either the urethral discharge or that pressed from the prostate as they were in the sedimentations from the urine. In the light of subsequent findings, this is significant.

On inserting the rectangular cystoscope into the bladder and taking a preliminary survey, I was surprised to observe what appeared to be two ureter openings to the left of the median line, on the line of the interureteric fold, about three-sixteenths of an inch apart, while another, single, ureter opening showed in the usual location on the right side. The three ureter openings thus seen were readily recognized by others present at the examination (Doctors Burford, Wolff, and Scharff). We supposed that the two openings on the left side were simply the duplicated outlet of a bifurcated ureter.

The right angle periscope was then replaced by the double-catheterizing part, armed with two catheters; a catheter was easily introduced into each of the two openings of the left side, passing upwards for what seemed about the natural distance to reach

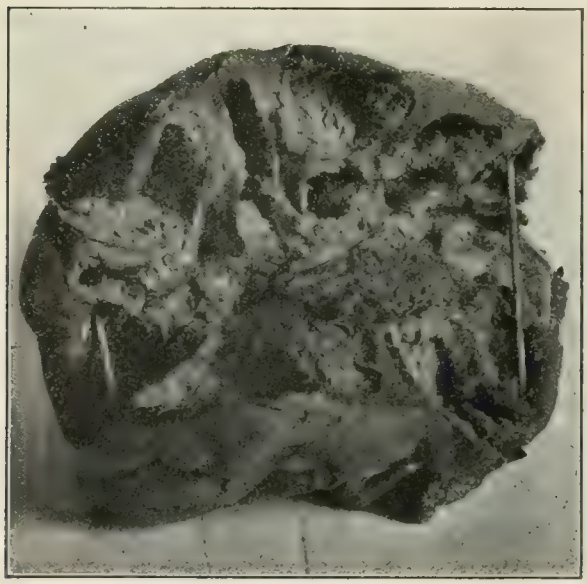

Fig. 2.--Destruction of kidney by gonococcal infection.

the kidney. They could not be felt to touch one another in transit. The ureter on the right side was left for future investigation, as my catheterizing attachment only provided for catheterizing two ureters at a time.

When the cystoscope was then withdrawn, leaving the two catheters in the openings on the left side, prompt drainage was established from both, the one draining the extreme left opening, however, being much more active than its companion. This latter, for convenience, we will term the middle opening.

The urines coming from the two catheters displayed not the slightest indication of having any relation to one another. One would drain regularly, after its own rhythm, while the other would follow *its* own periodicity quite out of harmony with the first. The extreme left one drained about three times as rapidly as the middle one. The urine coming from the extreme left opening was of much lighter specific gravity (1.005) than that from the middle (1.010); it was much lighter in color, was quite cloudy, with flocculi floating in it; while the other was clear and yellow, more like normal urine. On microscopical examination the left ureter urine showed much pus and epithelium, and a moderate number of blood cells, and, contained in quite a number of the pus cells, were colonies of diplococci that gave the customary appearance of gonococci to the positive methylene blue stain, and decolorized after the Gram stain. In the urine from the middle opening, no pus cells and no organisms were found.

After obtaining sufficient urine from both ureters to make the required tests, a colored silver solution was injected into the left catheter, the pelvis receiving something like three drams without causing pain or reaction, and, at the same time, the other catheter continued to drain the same as before, with no silver stain appearing and no interference with the rhythm of its drainage—giving additional evidence of the total independence of the two sources of urines coming from the two catheters. When we came to inject the silver solution into the catheter from the middle ureter, fifteen minims were sufficient to induce colicky pain in the left renal region, showing that that pelvis had nothing like the capacity of the other.

Two days later, February 24, the ureter of the right side was investigated, together with a repetition of the catheterization of the infected, extreme left, ureter. No pus or infective organisms were found in the urine of the right kidney, and its secretion of urine was even more active than that of the left, while the quality of its urine was also better (specific gravity 1.010). It was observed at this second catheterization of the left (infected) ureter that there had been marked decrease in the amount of pus that it contained; and, more important still, no gonococci were to be found in it. This pelvis was again washed with the silver solution.

Three days afterward, February 27, I carried out the excellent plan suggested by Kolischer and Schmidt for identifying the ureters throughout their course by means of lead fuse-wire filling the ureter catheters that are passed up to the kidneys, and made evident by an *x*-ray photograph. Three catheters, armed with wire, were successively introduced into the three ureter openings and pushed up toward the renal regions, after which two *x*-ray photographs were taken by Dr. R. D. Carman, with very satisfactory results (Fig. 1). This skiagraph makes it evident that the ureter on the right side of the body has no connection with the two on the left side. Those of the left side, after leaving their respective openings at the angle of the trigone, run parallel with one another in following the direction of the pelvic hexagon, and ascend in the manner usually followed by the left ureter. Whether because I did not push it as far as possible or not, one of the catheters ends at a point something like three inches lower than the other. It will be noticed, too, that, instead of the two ureters maintaining their relative positions, they cross one another in making their ascent. The one starting from the median vesical opening leads to the outer side when it reaches the flank, while the ureter that starts from the outer opening crosses and obtains the median position in the flank. This is the one that was infected with gonococci, the other two having been perfectly healthy.

The facts thus developed would seem to furnish ample explanation for the clinical incidents of the case—the continual recurrence without new exposures, over a period of five years, notwithstanding the judicious and comprehensive measures applied to the genital and lower urinary tract. Both Dr. Crook and the patient were repeatedly mystified as to the source of the renewed infection, that came like a thief in the night, apparently without cause or reason.

The silver irrigations of the infected pelvis brought the result desired. Evidences of infection that, up to that time were persistent, almost immediately disappeared, and the urine as quickly became clear. The patient left for home within a week afterwards. Dr. Crook and the patient both write that there has been no recurrence of the trouble, although treatment has now been discontinued for over seven months (since February, 1906).

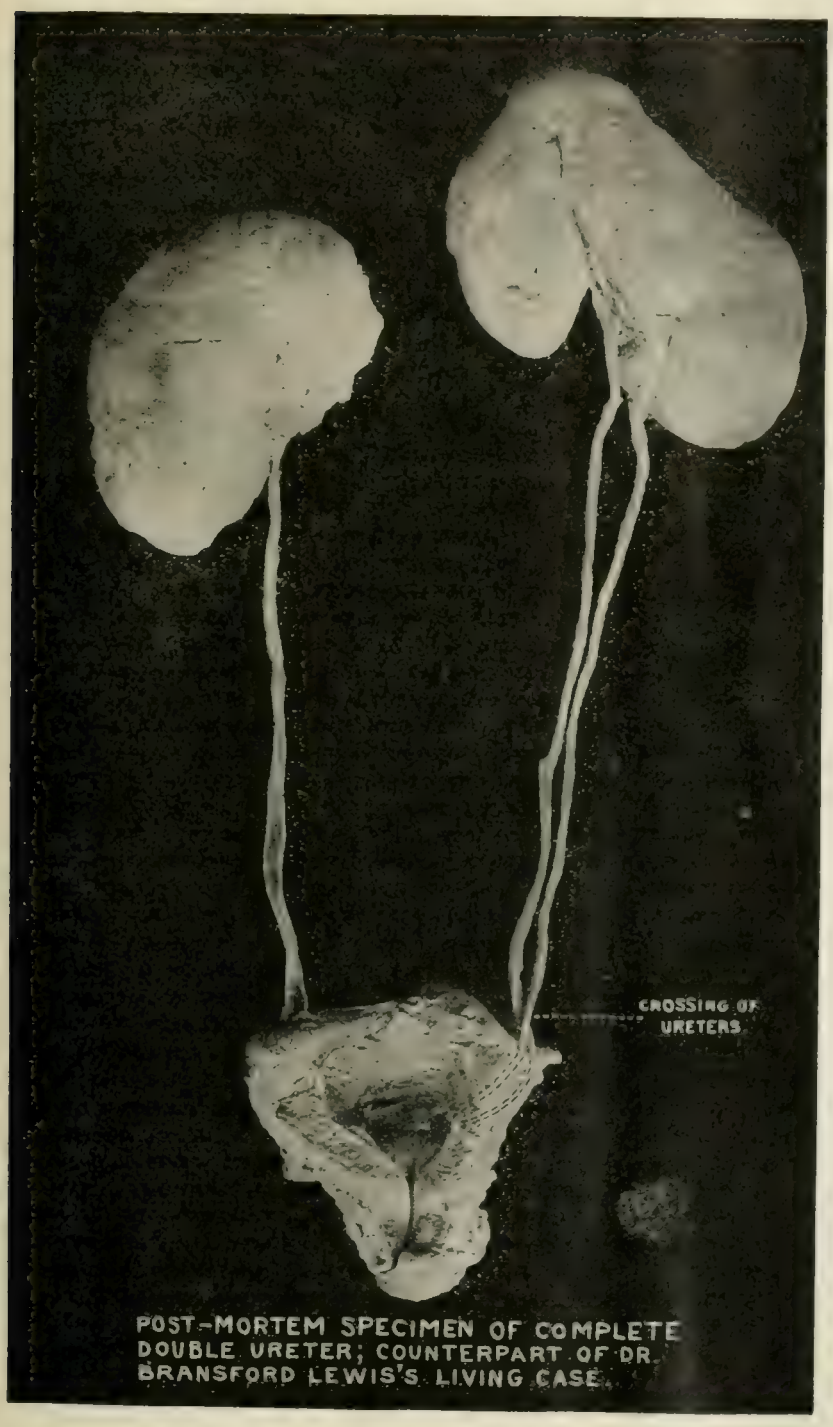

FIG. 3.

Infection of the kidney-pelvis by gonococci has, of course, been established by a number of well-attested reports. I have in my collection a kidney (Fig. 2) that was found on post-mortem to be a mass of suppurating tissue, the result of gonococcal infection, as proved by culture methods, by Dr. R. B. H. Gradwohl of St. Louis (reported to the American Association of Genitourinary Surgeons in May, 1900; *Journal of Cutaneous and Genitourinary Diseases*, September, 1900).

But the striking singularity of the present instance is the involvement of only one of two ureters that run, side by side, to the left renal region, the other ureter remaining free of infection. It would have been less surprising if both ureters thus closely associated had been found infected.

Aside from the interesting phases relating to the infection in this case, the anatomo-physiological question arises as to the source of the three kinds of urine obtained through the three catheters; as to whether there are two separate and independent kidneys on the left side, or only one kidney, that is divided into two parts and drained by two separate pelves and ureters. I believe the proof is furnished that there are two independent pelves, as well as two ureters. The marked differences in the two urines suffice to determine that. As to the other question, we must be guided largely by the study of other cases of this kind. Morris says ("Surgical Diseases of the Kidney and Ureter," Vol. 1, page 81) that supernumerary kidneys are extremely rare, and are usually found accidentally after death, as they do not give rise to any symptoms which indicate their presence during life. He quotes, however, a case recorded by Watson Cheyne (*Lancet*, 1899, Vol. 1, page 215), in which the supernumerary kidney was discovered during a laparotomy. "It was well developed and situated on the right side of the lower part of the spinal column at the brim of the pelvis. It had its own ureter and blood supply, and was from three to four inches distant from the right kidney, which was apparently of normal size. The left kidney was also present, and seemed rather smaller than the right. The third kidney, in this case, was quite movable."

While the *possibility* of an independent third kidney is thus established, study of specimens of duplicated ureters leads to the conclusion that there is much greater probability of there being only one kidney on the left side, in this case, with two pelves and their separate ureters. Byron Robinson has made a study of thirteen specimens and presented a valuable report on them (*Medical Fortnightly*, March 10, 1904). He finds that such eccentricities of anatomy have certain features of regularity, even in their irregularity. That but one kidney gives rise to two pelves and two ureters; that the ureter connected with the upper pole of the kidney (called the proximal ureter) habitually crosses behind the other ureter and terminates in the opening farthest from the urethral outlet of the bladder; while the distal ureter, leaving the lower pole of the kidney, crosses in front of the other one and terminates in

the opening nearest the urethral outlet. That arrangement is adhered to in the post-mortem specimen, the illustration of which I present herewith (Fig. 3), and it seems also to be followed in the case described above, as shown by the *x*-ray photograph (Fig. 1), where the crossing of the ureters is clearly seen.

It has been found in a number of specimens that the two poles of the kidneys and their respective pelves and ureters are separated by wedges of embryonal tissue, other than the normal kidney structure. Such a separation may make an effective barrier against extension of infection from one pelvis to the other, and account also for the wide differences in the urines draining from the two ureters of the one kidney, as displayed in this case.

I am aware that it is not remarkable to find duplicate ureters in the course of post-mortem examinations, such as is shown in Figure 3, but I have been unable to learn of any previous instance in which three different urines have been drawn from the same living individual, nor of an instance in which one of three ureters has proved the source of recurrent gonorrhea.

The permanent relief of such a case could be secured only by the elimination of the infective organisms from the upper urinary tract.

627 Century Building

AXIOMS IN THE TREATMENT OF CANCER OF THE RECTUM.

By CHARLES B. KELSEY, M.D.,

New York.

Judging solely from my own experience in practice, there seems to be great uncertainty in the minds of the profession at large as to the general principles which should govern in the treatment of that unfortunate condition, cancer of the rectum. Or, perhaps it would be better to say there seems to be a great divergence of opinion with a great deal of certainty, and a tendency on the part of each one to back his opinion—some for one form of surgical interference, some for another, and some for none at all. Twice within a week I have been sent for from suburban hospitals to throw whatever weight my opinion and advice may have, either for or against any operation, or in favor of some particular operation, where there was a very evident difference of opinion; and this happens not infrequently. One was a case which to me was manifestly inoperable, where the pelvis was fairly filled with carcinoma adherent to everything, and in which it was proposed to do three operations—first, a preliminary, provisional colostomy; second, a subsequent extirpation; third, a closure of the artificial anus. The other was very similar, but here the only difference of opinion was whether to extirpate or be content with colostomy.

This is not, perhaps, the worst feature of the situation, however. One case, in particular, I have in mind, where a life, which I had every reason to suppose might be prolonged for years and in which I hoped for a radical cure, so favorable was the growth for complete removal, was simply thrown away, because a physician who had never been asked to see the case told a member of the family he had seen a man die on the table from that operation. No doubt he had. I never have had that unfortunate experience, but there is no doubt he represented a large class of physicians who have seen or heard of fatal cases of attempted extirpation, and who are so prejudiced against the procedure for this reason, that they are honestly ready to throw their weight against it whenever they get an opportunity. It is for this class of men I have here attempted to set down certain plain, guiding principles based upon facts, principles which govern my own practice, and which I believe to be safe, sound, and for the good of the patient.

Let me start with a very simple proposition, which I think can give rise to little discussion. Operable cases of cancer of the rectum, like cancers elsewhere, should first be treated by a radical attempt at cure, which means removal. And I hasten to add that, to my mind, only such cases are operable as allow of complete removal of the disease with no more risk than attends any other major surgical operation.

The corollary of this proposition is that inoperable cases should not be treated in this way, but by other and better methods.

To be more exact in our definition of operable and inoperable: Any cancer of the rectum which is movable, which is still confined to the rectum, even if in all its coats and to the surrounding cellular tissue, even though it may be attached slightly to prostate or vagina, offers a chance of cure, and should be treated by radical operation. Any cancer of the rectum which has involved the surrounding tissues (prostate, bladder, vagina, uterus, or bony points of pelvis) to an extent which makes a hard, immovable mass on digital examination is inoperable. This distinction is not arbitrary. It simply means that in one case we are dealing with cancer of the rectum, in the other with cancer of the pelvis. No reference is made to the particular point of the rectum involved, whether high up or low down, because with modern technique this is not essential. Removal of cancer of the upper rectum or sigmoid is no more dangerous than the removal of the lower third of the gut.

We may now go a step further. A cancer may be inoperable because of its extent and attachments, but not all circumscribed and unattached growths are therefore operable. Age, general health, almost every condition in the patient's life and surroundings, must be taken into consideration. Given a man of eighty, whose only symptom is an annoying frequency in the desire to have a passage, and who suffers no pain, is it wise to attempt an extirpation? I think not. It is unpleasant, to say the least, to put a patient through an extirpation of the rectum, and find a metastasis in the liver a fortnight later, although it may happen to the best diagnostician. It is also unpleasant to open the abdomen and find a little previously undiscovered ascites, for this also means metastasis, and all of these things have to be considered and carefully examined in reaching a conclusion as to the form of surgery, if any, to be advised. Again, to decide this question wisely, we must know something in a general way of the risks and results of operative interference, even in carefully selected cases. What is the risk? What the results as to cure or prolonging life in comfort? What the chances of recurrence, and how soon? Can anything better than extirpation be done, and what? All of these questions must be answered to the satisfaction of patient, attending physician, and family.

The simple fact is that extirpation of the rectum is not an operation of any great mortality when done by suitable men. And yet, if some of the cases I see in consultation are operated upon, in spite of my advice, as I suspect they are, the mortality may well be frightfully high, and death on the table, or very near it, rather to be expected.

The rate of mortality will depend upon the choice of cases and the operator. At St. Mark's it is now a little under 3 per cent., and my own is about the same. But it is evident both they and I are selecting our cases very carefully. When I began to operate my mortality was 33 per cent., and so was Kraske's. In a miscellaneous group of cases it is about 22 per cent., but these figures have no value. We all know of the operation whose mortality after one case was a hundred per cent., and I honestly believe this has applied more frequently to extirpation of the rectum than to any other operation.

And now as to results. How often may we hope for radical cure? More frequently than is generally known. I passed a gentleman driving with his wife in the park yesterday, well, happy, and prosperous, occupying a position of great responsibility, from whom I removed a cancer of the rectum ten years ago. There is a physician not far from New York, still doing a large and active practice, who, when I was obliged to tell him the diagnosis no longer admitted of a doubt, turned to his wife, and said simply: "This is death." That, also, was about ten years ago, and the case was not a slight one, but involved the prostate. Other patients I have that report to me occasionally, in whom the interval is fully as long, and some of half that time. Other men have equally good results, and in the aggregate they make a goodly number. So we know that, like cancer elsewhere, it is sometimes curable by operation, even when such a result seems hardly to be expected; and that certain varieties, when favorably situated (epithelioma near the verge of the anus) are generally curable in their early stages.

But cancer of the intestine is an unsatisfactory disease, no matter what its form or where situated, and suppose we fail to cure, we at least do good. For extirpation in many cases, even with a rapid recurrence, is a great palliative, and is fully justified from that fact alone. It may even be done more than once, and a recurrence may be cured when the original operation has evidently not cured; and so may life be prolonged and suffering avoided.

It must be evident that I am not speaking of an operation of any very great mortality in itself; of procedures which result in death on the table, and from which patients seldom recover. I am simply speaking of the operation of excision of the rectum, as practised to-day on cases selected with care by conservative surgeons.

What is the best form of operation? There is none that is applicable to all cases, and the site of the growth must be the controlling factor. Some very low down may be reached best from the perineum or vagina and amputated, although I judge from Goodsall and Miles' work that at St. Mark's they have practically cut loose from Allingham's teaching and perineal method, which was the one most practised for a long time. In cases involving the middle and upper thirds, some form of sacral incision is unquestionably the best, and in cases still higher the operation may be abdominal, or a combination of this with one of the others. There have been many different procedures described which cannot even be enumerated here, each having its advocate; but in the vast majority of cases the operation will be an exsection of the affected part through a sacral incision, with or without subsequent anastomosis. Goodsall is advocating and practising very successfully at St. Mark's a very radical procedure, which, in spite of its permanent colostomy, may yet prove the simplest and best. It consists, first, in colostomy two or three weeks before the excision and the formation of a permanent artificial anus, then of sacral removal of the entire rectum and anus, no attempt being made to preserve the natural anus or any gut below the disease, and, finally, a complete closure of the dorsal and perineal incisions.

In spite of its manifest disadvantage, the permanent artificial anus, which I have always avoided, I confess that this method appeals to me very strongly. The technique of the operation as to the removal of the growth is that which I have practised for years, but after resecting I have generally found it possible to establish some sort of anus (mostly artificial) at or near the natural site, and have, therefore, been able to avoid the preliminary colostomy, and also to complete the operation at one sitting. But, then, the recurrences have almost invariably been in the anal portion—which has been left—and the entire removal of this, with the fat and tissues in front of the sacrum and in the ischiorectal fossæ, may reasonably be expected to give greater immunity. Goodsall states the points in favor of his method very forcibly as follows: After excision of the rectum an artificial anus must result, and in consequence there must be some considerable degree of loss of power of control, whether the interischial, the sacral, or the abdominal variety has been adopted. During the healing of the excision wound feces are not voided through it, thus saving the patient much discomfort and pain, as well as delay in the healing. Further, there is no necessity for subsequent dilation, and this is important as avoiding irritation, and hence liability to recurrence. The wound often closes completely, and there is no discharge in the anal region. If recurrence takes place there is no irritation from feces. The risk of pelvirectal suppuration, following recurrence, is diminished, as is that of hemorrhage. The weight and health improve much more rapidly than in cases without preliminary colostomy.

Every operator, in making his choice, will be influenced in a measure by his sentiment toward colostomy. This and the fact of a double operation have always led me to forego the manifest advantages which a preliminary artificial anus offers; for, though always advocating and doing colostomy when necessary, and fully appreciating its advantages, I have never thought it necessary as a step in the operation of excision. But, if it has any bearing on the question of completeness of removal, subsequent relief from irritation and especially upon the liability of recurrence, as Goodsall holds, no one is justified in refusing it.

With the exception of the colostomy, and the complete removal of the anal portion, it seems that he has followed for some time the technique adopted by me at the Post-Graduate years ago, when I gave up the perineal method. Briefly, the essential points are the attack upon the growth from behind and above through a sacral incision, the avoidance of bleeding, and the saving of time, and hence of shock in the operation.

The names of the different men who have each recommended a slightly different incision through the sacrum (Kraske, Hochenegg, Rydygier, etc.) are well known, but the differences are not important. If my own is like any of them it is nearest to Bardenheuer's, that is, a transverse section through the sacrum above the last spinous process, but the essential thing is to get down to the rectum quickly and completely without uncertainty or delay.

Make a long incision with one stroke of the knife, reaching down to the bone from near the level

of the middle of the sacrum to the anus, and make this in the median line. Dissect the flaps rapidly from the lower end of the spine, for a short distance push one blade of a large bone forceps under the sacrum at the level described, cut the bone across, seize the detached fragment of sacrum and coccyx with a strong-toothed forceps, dissect it free of its attachments, plug the cavity with a sponge, and the first step of the operation is completed. Now this may be a matter of minutes, or of an hour, according to the personal equation. With myself and the assistants, who have been specially trained by me, it is a matter of a very few seconds, and the reason is that I want to get a big sponge into the pelvic cavity to control the bleeding as soon as possible; therefore there is no tying of vessels, and remarkably little blood. In fact, no vessel may require a ligature either now or till the rectum has been removed.

After a short breathing space to see the effect of the pressure, during which the heavy instruments so far used are removed and a goodly supply of artery forceps substituted with scissors, a fresh, sharp knife to replace the one which will need grinding, ligatures, etc., the sponge is quietly removed. Often the wound will be perfectly dry and not an ounce of blood has been lost. Sometimes there is a nasty, continuous, venous oozing from the plexus of veins on the hollow of the sacrum where the bone has been cut across, and two or three forceps may be necessary to control it. These may be left *in situ* till the operation is completed, or the points may all be tied in one ligature.

The posterior surface of the rectum is now directly in the wound, and the next step is to isolate it from its surrounding tissues by blunt dissection. Use the finger first on the right side, then on the left up and down from the attachment of the peritoneum to the levator, for these are the two points at which the gut will be most firmly held, and then deliberately tear through the peritoneum at the upper right hand angle of the wound, pass the finger into the peritoneal cavity under the upper part of the gut from right to left, so that the gut lies in the crook of the index finger, and either by blunt or sharp dissection (the latter may be necessary when the serous fold is heavy), loosen the peritoneal attachment from the bowel, and bring the latter down. The gut will not come down while the peritoneum holds it, and traction to make it do so often results in rupture. But the moment the peritoneum has been divided the whole upper rectum, and in fact most of the sigmoid, are at command, held only by the mesorectum and mesosigmoid, which may be divided to any extent necessary after ligature. This completes what may be called the second stage of the operation; the wound may be freely bathed with hot water to prevent oozing; sponges are placed at its upper angle to close off the peritoneum and keep back coils of intestine; the extent of the growth above is determined, and the gut is divided between two tapes at least one and a half, and better two full inches above the upper limit of the growth, every care being taken not to soil the wound with feces.

If a permanent colostomy has been done, the upper end should be transfixed with a double ligature, and dropped after the mucosa has been cauterized with carbolic acid or the Paquelin. The removal of the lower segment, with or without the anus, is not difficult, the chief obstacle being the insertion of the levator, which must be cut with scissors all around. Free division of the anal portion in the median line behind may be a great help, and even necessary for satisfactory removal of the growth. If the prostate is involved a sound should be passed into the bladder. If the vaginal wall has become implicated it should be excised, and since recurrence is always to be feared a careful search for enlarged glands in the presacral connective tissue and around the growth in the connective tissue should always be made, and as much of this tissue as possible removed.

I have never been sure that attempts at end-to-end anastomosis after this operation paid. I have never seen it succeed very well, except where the disease was high enough and limited enough, so that both ends were covered with peritoneum, and I am usually content to stitch the upper end to the skin as near the point of the natural anus as possible, or to remove the mucosa from the natural anus and stitch it there.

Should this be adopted the time of operation is greatly shortened. The wound in the peritoneum may be sutured or not (it is not essential); the whole large cavity formerly occupied by the rectum should be washed out with hot water; deep sutures may often be used to advantage; a gauze drain should always be left in, and the wound closed.

Never place the patient flat on his back to lie upon the incision, or the flaps may easily slough from pressure against the sacrum in a few hours.

This, then, in brief is an outline of the operation I have found most satisfactory for many years, and more than once I have completed it in fifteen minutes with scarce any hemorrhage or shock, which must certainly have an influence on the mortality. Excepting that I am much impressed with Goodsall's argument in favor of complete removal of everything below the growth, I see nothing better in cases to which it is applicable, and it is applicable with modifications as to anastomosis to nearly the entire rectum and sigmoid.

Very satisfactory results may sometimes be secured where the tumor is high enough and sufficiently limited in extent, so that after resection both ends may be united without interfering with the natural anus. We have called attention to the fact that the anus made after extirpation, no matter how ingeniously constructed or where placed, even though the natural orifice be utilized, is still an artificial one attended by incontinence. But where it is possible by abdominal or sacral incision, or by both combined, to resect and anastomose without interference with the spincteric portion, we have the ideal operation. Under these conditions, which are rare, any form of union may be practised—end-to-end suture, Murphy button, bone or vegetable bobbin, lateral suture, or invagination of the end of the proximal portion into the side of the distal. All of them, unless the growth be high enough in the sigmoid to be easily reached by abdominal incision, can best be done by the sacral incision, for the simple reason that any delicate work in this line deep in the pelvis, where one section of the gut is very nearly fixed and immovable, is most difficult through an abdominal incision alone. The easiest, manually, is implantation of the upper end into the side of the lower, because in this the work is facilitated by utilizing the rectal cavity as a means of approach.

Palliative Treatment.—Try as we may, and seek for substitutes where we can, there is no getting away from the fact that colostomy is the greatest of all palliatives for cancer of the rectum. For a quarter of a century it has held its own, and it will continue to do so in spite of natural prejudices. There

is no advantage in argument on a subject which may be considered as thoroughly argued out. I have the records of two cases, one with Park of Buffalo and one with Bull and the late Dr. McCreery of New York, in which the lives of very prominent men were prolonged in comparative comfort for five years after the disease had so far progressed as to be inoperable. Both were men of wealth, able to command every care, and of course this helped in the result; but think of a gentleman going South for a fishing trip vacation from the cares of active business three years after this operation, and having still two years more of life before him, most of it fairly comfortable, and find something better if possible. As I say, both of these cases were already too far advanced for extirpation when the operation was performed. But these, though exceptional, are not so phenomenal as to be useless as a basis for prognosis. Excluding abdominal metastasis, I expect to get from one to three years of prolonged life from a colostomy, and tell my patients so. Moreover, I am quite as anxious to earn the gratitude of my patients as are other men, and were those upon whom I operate the objects of disgust to themselves and the world they are pictured in imagination, I should not succeed. On the contrary, they are among the most grateful.

If colostomy does good, not simply as overcoming intestinal obstruction, which, by the way, is a very rare complication of cancer, but by preventing irritation, stopping bleeding and discharge, and postponing the inevitable end by sidetracking the diseased part and removing it from any participation in the economy, then the sooner done the better. Colostomy as "a last resort," done after obstruction, has begun to be evident, to prevent threatening dissolution, is an operation of high mortality, and when successfully done will not result in any such lengthening of life, as I usually hope to secure. With me it is the *first* resort after extirpation is decided against, and should be done without delay. Under such circumstances the risk is the same as after other laparotomies, comparatively *nil*—say one or two per cent.

In cases of chronic obstruction there may be a choice of site for the colostomy—left, right, or transverse. The left is always to be chosen by preference, other things being equal, but I have seen the entire colon so solidly packed with feces that it was impossible to get any relief, even after a very large and free opening into the sigmoid, and my patient died on this account. In the effort to relieve him through the artificial anus an olive pit was brought to the light, which he was positive dated from a cocktail more than a year previous. If his memory was correct, as I have no doubt, this fact is worthy of notice in the history of intestinal obstruction.

Under such circumstances a right inguinal operation upon the cecum, as far from the valve as possible, is indicated; but the entire colon should not be shut off from the economy, except for very good reasons. It certainly has its functions.

As for other palliative treatment—curettage, cauterizing—although these may seem to check the discharge for a short time, they are so far inferior to colostomy as to offer no comparison. Moreover, I am timid about them, having seen one fatal case of hemorrhage and having a suspicion, which of course cannot be verified, that in more than one case they have been responsible for rapid and immediate metastasis. We do not know very much about cancer, but the tendency of modern surgery is certainly to cut wide of it and not to stir it up with a curette. Witness the results of the modern operation for cancer of the breast as compared with those of a few years ago. The success seems to be due in great measure to avoiding all chance of reinfection, even during the act of extirpation.

In what has been said the intent has been to enforce certain general principles and avoid details.

1. Every suitable case of cancer of the rectum should be subjected to immediate excision or resection by some of the half dozen well-recognized varieties of the operation.

2. Every other case should be at once treated by colostomy.

3. No physician is justified in using his influence against some form of operative relief, radical or palliative.

THE TREATMENT OF SYMPTOMS A RATIONAL AND SCIENTIFIC PROCEDURE

By GEO. F. BUTLER, M.D.,

CHICAGO.

PROFESSOR OF MEDICINE, POST-GRADUATE MEDICAL SCHOOL.

THERE is a quite general unscientific conception among medical men regarding therapeutics, namely, that there is a specific for particular diseases and that self-limitation of a disease is an absolute law. This generally accepted belief as to self-limitation ignores certain definitely determined principles of etiology which go to show that a disease is the result of three factors. It is, the product, first, of the determining cause; second, of the condition of the patient at the time that the cause is applied, and third, of the general condition of the patient dependent on his congenital constitution. The existence of what are called *formes frustes* or aborted forms of disease in which conditions varying from the disease type occur, indicates that there are factors which interfere both with the self-limitation and with the manifestations of such diseases. There are "walking" cases of typhoid fever, of pneumonia, of smallpox, of scarlet fever, which indicates that the vitality of the patient is not affected to the degree it should be, according to the ordinary conception of self-limitive conditions. Indeed, this constitutional factor plays a part in the results of cardiac conditions, including wounds of the heart. The question in the cardiac state is not the existence of the given lesion or even the extent of it, but rather the degree of compensation. The older conception that heart wounds were absolutely fatal was proven seventy years ago to be entirely erroneous. Indeed, to-day no surgeon would accept it, since 40 per cent. of the cases of heart suture are successful. The problem, therefore, in the treatment of disease, is to determine whether conditions which produce modified constitutional symptoms are to be obtained by medicinal agencies.

The elements which may be affected by treatment are the course of the disease, the general constitutional vitality, and the constitutional vitality of the patient at the time of the attack. These factors may be influenced by "symptom remedies," so-called, applied to conditions produced by the diseases and which tend to reduce the congenital and acquired vitality. In certain cases fever is a factor which tends to reduce the

general strength and to exhaust the patient. When we lower the temperature we interfere with a factor which is sapping the vitality of the patient and decreasing his resistance to disease. Reduction of the fever, therefore, is a problem in such cases to be studied therapeutically. The temperature of the body depends upon a complicated mechanism which is at once thermostatic, thermoinhibitory, and thermoexcitory. Hence, an elevation of temperature may obtain on exhaustion of the thermoinhibitory and the thermostatic centers and not upon stimulation of the thermoexcitory centers. Here, a totally different class of agents is indicated from those needed where the thermoexcitory functions are increased. As increased tone given to the circulation and the heart benefits the former class of cases, hence agents increasing cardiac tone are indicated. The reverse is the case where thermoexcitory functions are involved. In these cases veratrine, aconitine, venesection, and even the coal-tar synthetics are indicated. The influence of cold sponging, through its action upon the skin and reflexly upon the circulatory apparatus, is peculiarly beneficial in the first type of cases. The fever, moreover, may be an expression of general nervous agitation. Here the drugs above mentioned often prove valuable without depressing the heart. As general nervous agitation in fevers is connected with insomnia of the coma vigil type, hypnotics are indicated, since the fever, nervous irritation and the insomnia work in a vicious circle to exhaust the nervous vitality. Indeed, until insomnia is conquered, it is useless to expect a relief of the other symptoms. In these cases the kidneys, which are under a tremendous strain from nerve waste, need attention. To neglect of these the most objectionable results of hypnotics are due. Hypnotics given to secure rest at a certain time when the nervous system is weak, particularly when they do not interfere with the renal elimination, act excellently on the agencies which are sapping the general vitality in these cases. As usually given, however, they are deleterious. Opium is objectionable for many reasons, as likewise are chloral hydrate, paraldehyde, etc. Since sulphonal, veronal, trional, etc., all produce an alterative effect on the blood, causing hematoporphinuria, which indicates renal strain, they are, when given alone, likewise contraindicated. They should be employed in combination with hyoscine, coniine, duboisine, and the opium alkaloids so as to prevent both the alterative action on the blood and the renal strain. The employment, therefore, of symptom remedies to produce constitutional results and to produce likewise an aborted type of so-called limited diseases is a logical procedure. Disease is not treated, but its effects on the system are so managed as to secure and maintain proper vitality. Pneumonia was formerly treated in many instances with greater success than at present since the self-limited conception has obtained. What is true of pneumonia is likewise true of typhoid fever, where the great indication is to prevent sapping of vitality. That typhoid fever is aborted, no one who has had extended experience with atypical cases can doubt. A careful study of these cases reveals the fact that they are produced by certain factors which therapeusis can mimic to a greater or lesser degree. The disease, however, must be studied from the standpoint of its effects on the given constitution and not from the generic conception of typhoid fever.

The autotoxic states come peculiarly under the same category, since the symptoms from the effects of the cause on the constitution attacked and the indications for treatment vary with the effects produced on the general constitution. Here the great aim is to secure proper elimination without strain on the eliminatory organs. These autotoxic states mimic almost every type of disorder not excluding those due to the bacterial toxins. A large number of recoveries in alleged bacterial disorders have occurred by the proper treatment of autotoxic conditions in which many of the clinical symptoms mimic those of bacterial origin. Scientific therapeusis, therefore, implies a proper study of both direct and untoward effects of drugs correlated with a study of the symptoms presented by a given case. Neglect to observe carefully the conditions underlying atypical cases is due to the belief in the absoluteness of the course of self-limited diseases. The fact that variation of the culture medium implies change in the virulence of a given germ should have shocked this alleged law to its foundation since it no longer explained the facts nor did it exclude other explanations, as scientific proof should have done. The fact that "symptom remedies" have been decried in the treatment of disease (another very popular medical error) arises from the unscientific conception that treatment of symptoms has no effect whatever on the constitution of the patient, and hence on the progress of the disease. The fact that symptoms at the very least may exhaust general vitality, and the further fact that it is upon the general vitality that the chances of recovery depend, have not been taken into consideration to the degree that they should be in the ordinary conception of therapeusis. Strictly speaking, the older belief that the physician does not cure disease, but guides the patient to recovery, is the essential basis of scientific therapeusis.

A nurse can give antidiphtheritic serum and treat a case of diphtheria as well, possibly, as a doctor, but in pneumonia and other diseases for which we have no specific a good physician, who can do things to maintain the patient's vitality, relieve his suffering, and guide him through to a successful recovery, is urgently needed.

I am weary of listening to the cold, hopeless words of the ultra-scientific doctor who says we can do nothing for acute diseases, they are self-limiting, and Nature will do all that is necessary to do, and it is "unscientific" to treat symptoms.

A storm at sea is self-limiting, yet we would feel very ill at ease if we were aboard a ship during a storm should the captain assume the attitude of some of the alleged leaders in the medical profession and do nothing towards guiding and helping his ship to breast the wind and waves. Let us have more common sense and optimism, even if we are accused by some of being "unscientific."

103 State Street.

The Form of Red Blood Cells in Mammalia.—Retterer divides the red blood cells into three classes: The small cells from three to four are spherical and essentially chromatic; the hemispherical cells are composed of a central chromatic mass, surrounded by a clear cirtical layer, the cortical protoplasm showing on one surface or the other a biconvex thickening; the semilunar cells have a central chromatic mass, the two surfaces of which are more or less hollowed out.—*Gazette des Hopitaux Civils et Militaires.*

THE EFFECT OF BLOWING UPON WIND MUSICAL INSTRUMENTS WITH SPECIAL REFERENCE TO TUBERCULOSIS.

By J. FREDERICK ROGERS, M.D.,

NEW HAVEN, CONN.

HOUSE PHYSICIAN NEW HAVEN HOSPITAL

It is a general belief among performers upon wind musical instruments that such exercise is beneficial to the lungs, and that such performers are more free from disease of the respiratory tract than the average run of mankind. The present article is an attempt to show what influence for good or bad this occupation has.

Physiology.—Blowing upon wind instruments is an act of exaggerated respiration with all the effects upon the general economy which this includes.

In playing any wind instrument the taking of the breath differs from the usual act in rapidity and depth. The performance of a melody, with due regard to the requirements of phrasing, requires that the interval between the exhaustion of the air and the succeeding intake be brief. The extent of the inspiration is always more profound than in ordinary breathing, but varies with the instrument and with the amount of air needed to give expression to the particular phrase of music. It depends also to some extent on the training of the performer. In individual private playing the breathing may be as suits the pleasure, though it is always deeper than usual. Every inspiration is not equally extensive, since the breath is often taken before the chest has returned to its usual capacity; but all the excursions are above the ordinary, varying from 5 mm. to 40 mm. or more, with the individual, the instrument, and the performance.

While the expiration is comparatively long, the respirations, as shown by mechanical records, are often about as many, per minute, as usual. In the playing of some kinds of music, and upon certain instruments, they may be more or less frequent than usual, but in private performance they must be as frequent as the performer wishes to make them. Compared with the act of reading aloud, they are more frequent.

The pressure developed within the lung during normal expiration, as shown by experiments of Donders (Landois and Stirling) is from 2 to 3 mm. Hg. The pressure in the lungs varies widely with the instrument and with the loudness of the tone. The pressure necessary for the production of tones in the most used instruments, in the compass of notes usually employed, I have found, by means of a mercury manometer, to be as follows:

	Played Softly.	*Played Loudly.*
Flute	2–4 mm	2–7 mm. Hg
Piccolo	3–12 "	6–24 " "
Euphonium	3–15 "	8–25 " "
Trombone	3–15 "	8–25 " "
B Clarinet	5–8 "	18–3 " "
E Tuba	13–21 "	16–28 " "
B Cornet	5–30 "	13–75 " "

Let us now make a comparison of the pressures in the various instruments with the pressures developing in singing. It has been found by Donders that the possible pressure within the lungs are from 80-100 mm. of Hg. The pressures necessary for the production of vocal sounds, as obtained in a case of tracheal fistula in a woman by Cagniard and Latour (Landois and Stirling), are as follows:

Whispering	–2 mm. Hg
Medium pitch	–12 " "
High pitch	–15 " "
Very high notes	–55 " "
Highest notes	–72 " "

It will be noted by a glance at the table that the production of tones on the flute corresponds with that used in whispering voice, while for vocal sounds the pressures correspond fairly with those of most other instruments.

Owing to the elasticity of the lungs and their constant tendency to collapse, there is maintained a constant negative pressure within the thorax and outside the alveoli, varying (as found by Donders) from —7.5 mm. of Hg. in the expiratory position to —9 mm. in the inspiratory position. With profound inspiration this negative pressure becomes as much as —30 mm. The circulation, both systemic and pulmonic, is greatly influenced by this condition in the thorax, the inflow toward the heart being aided in proportion to the degree of minus pressure. With the unusual expansion preparatory to blowing upon a musical instrument, this negative intrathoracic pressure is greatly increased above that of ordinary respiration, and there is a concomitant greater suction of blood into the right heart, and the heart is quickened from the increased supply of blood which it must get rid of.

With the expiratory act the negative pressure in the chest (extraalveolar) diminishes in proportion to the amount of positive pressure developed within the lungs (intraalveolar). There is then a checking of the previously hastened venous flow to the heart; but since the negative pressure developed within the chest corresponds to the degree of distention of the elastic air sacs, it will require a high degree of pressure to be developed before there will be actual obstruction to the return circulation. That this return flow may be interfered with is shown by the swelling of the veins of the neck and the growing red in the face in the cornet or trumpet players where a high note is long sustained. (See pressure required in table, above). With instruments requiring less degree of pressure there would be no interference.

Since the same conditions prevail everywhere in the chest outside the alveolic, the circulation within the lung substance will be influenced in a similar manner. Summing up other physiological effects: the outflow of lymph is hastened, especially from the lung tissue; the heart sounds and beats are not materially altered except by extreme pressure; the gaseous interchange in the lungs must be facilitated, at least temporarily; the effects of changes of pressure upon the circulation and movements of the abdominal organs are pronounced; the amount of muscular strength required varies with the instrument and character of performance.

The Musician and His Surroundings.—Musicians may be classed as professional and amateur, or those who make music a business and those who make it a pastime.

Of the first group it is demanded that they, besides having the requisite skill otherwise, shall produce a sufficient volume of tone, and that they shall play as many hours as the organization to which they belong requires. Professional musicians, again, may play in the military bands which perform in the open air through the summer, and in winter in fairly hygienic conditions indoors;

they may belong to theatre orchestras, sitting beneath dust laden draughts blowing from the stage floor, or rehearsing in cold rooms, or playing for dances in dusty halls, and going out, overheated, into the chill of the early morning. Lastly, a few of sufficient virtuosity play under good hygienic conditions with the few great orchestras of the country. Of these, however, the utmost skill in the production of quality and quantity of tone is demanded, for which they must be physically competent. In all the various employments, therefore, a comparatively strong physique is necessary, while the hygienic conditions are not always ideal.

The amateur musician has no demands upon him save those self imposed. He can play under the best conditions, as little or as much as he pleases, and with as much or little volume of tone as suits his physical powers. Frequently he joins himself to some amateur band or orchestra for the added pleasure so derived. In perhaps the majority of such organizations the greatest pleasure comes from hearing one's own instrument sounding above all the rest, so that the performance comes to be a competition as to which can play the loudest. The pressure within the lungs so developed is so great that it is truly astonishing that all the pathological conditions imagined by Robillier, and many more, do not occur every day. Frequently these men practice in underheated or overheated rooms, with a foul floor, and breathe an atmosphere laden with tobacco smoke.

As a class, musicians are perhaps more addicted to alcohol than men of other professions, and this should be taken into account in connection with any pathological conditions to which they may be susceptible.

Pathology.—In all works on pathology blowing upon wind instruments is given as a cause of vesicular emphysema; but, so far as I have been able to learn from correspondence with pathologists of wide experience, there are no records of post mortem findings substantiating this statement.

Since breathing in emphysema is so modified, one would expect that such a condition would incapacitate a musician from following his profession, but I have been unable to obtain data from the leaders of bands or orchestras on this point. The recent investigations of Prettin and Liebkin (*Münchener medizinische Wochenschrift,* February, 1904) are interesting in this connection. In their examination of 230 glass blowers who had worked at their trade for many years, they found only five of these to be emphysematous.

Dr. W. Gilman Thompson in "Text-book of Medicine," 1902, makes this statement: "The extent to which forcible expiration against obstruction, as in the blowing upon wind instruments, blow-pipes, etc., aids in over expansion of the air sacs has been much overrated. As a primary cause of emphysema, it probably has no influence, but as a secondary cause, when the lung circulation is impaired and connective tissue tends to replace certain normal lung tissue, it may have force. My colleague, the late J. West Roosevelt, examined the chests of all the blowers upon wind instruments in several large metropolitan orchestras without discovering a case in many years. Beer-drinking workmen or musicians with a cirrhotic diathesis may develop emphysema; but its primary cause is, then, the chronic alcoholism, and not the occupation." There is, then, apparently no evidence, pathological or clinical, that playing upon wind instruments is, in itself, a primary cause of emphysema.

Pathological Physiology.—Except as a cause of emphysema, I have found no mention in any works on pathology or medicine of any injurious effects following this exercise. In looking through the Army Medical Library in Washington, D. C., I came upon a suggestion of possible results in Robillier—Recueil de Mémoires de Médecine, de Chirurgie et de Pharmacie Militaires, Paris, 1825, Vol. XVI., p. 56—De L'Influence des Instrumens à vent, en cuivre sur la santé des soldats qui en font usage. I quote from it as follows:

"Among the pathological effects which may result from prolonged exercise on the clarion, cornet, and trumpet, are those on the circulation and on the lungs. The robust men with large chests become habituated, and do not suffer bad effects; but those of feeble constitution and narrow chests, those who are very full-blooded (*tres sanguins*), who have a short neck and who are large and thick set, experience, after having devoted a long time to a wind instrument, the oppression of suffocation, as if they had just been running.

"These effects come not only from the fatigue of the agents of respiration, but from the stasis of blood. This stasis of blood in the chest, likewise the frequent and rapid passage of air through the bronchi, can become a predisposition, and even a cause of catarrh, pneumonia, and, consequently, of phthisis.

"May not the engorgement of the blood in the right cavities of the heart, occasioned by the difficulty of passage through the lungs, produce at length hypertrophy and dilatation of the right ventricle? May not the reflux of the blood arterial and venous, during the long expiration, produce cerebral congestion and become a cause of apoplexy? Lastly, may not the tension of the muscles of the abdomen, with the pressing down of the diaphragm, produce hernia?"

While the breathlessness mentioned, and sometimes the dizziness, does occur, it is only with violent exertion, or where tones must be long sustained at a very high pressure, and it is probably not more serious than the breathlessness from running. In producing apoplexy it might, just as any similar exertion, as in lifting a heavy weight or straining at stool, produce the finishing touch to the preceding degenerative condition. This, and the other effects mentioned by Robillier, must occur with extreme rarity.

Bulbar paralysis is mentioned by neurologists as being sometimes the result of the continued use of the tongue and lips in playing. Dr. Chas. L. Dana writes me that "among a pretty long list of cases of bulbar paralysis, I have had perhaps one or two in which it seemed as though the cause was that of playing on wind instruments. . . . I should not consider a musician in any danger from bulbar paralysis, unless he had had syphilis."

There is a prevailing belief among musicians that performers on the oboe are subject to mental peculiarities. Mr. F. N. Innes, Director of Innes' Band, writes me: "There is doubtless a great deal of nonsense about this belief, but the belief is certainly prevalent, and I should personally say that my own experience has tended to confirm the belief that, in the cases of a small minority of players on this instrument, the effects as stated apply."

Mr. Arthur Brooke, of the Boston Symphony Orchestra, told me of an oboe player in London, who, when tried for a theft, pleaded not guilty on

the ground that his act was the result of a mental condition produced by his professional work. The condition, if it exists, has been attributed to the fact that the air is forced through a very small aperture, and so the expiration is unusually prolonged.

It seems hardly possible that any such mental effects could follow from this cause in an instrument which requires so little pressure within the lungs. It would seem that the quality of tone of this instrument, and the character of the music which is most frequently given to it, might seem a more possible cause for any such mental condition, if it exists. That there is no decrease in longevity among such musicians is suggested by the fact that an oboeist ninety-two years old recently played at a public performance in Boston.

Correspondence.—At best our knowledge of physiology is very limited, and the bodily machinery does not always obey to the letter the laws we would lay down for it. The results of experience are, therefore, of first importance in this study. In the hope of obtaining information as to the results of this exercise, I have written to a number of physicians who, from wide clinical experience, might be expected to have made note of any especial tendency to disease among such musicians, and to directors of bands and orchestras, teachers of wind instruments, and others who have had a wide and intimate knowledge of members of the profession.

That performers on wind instruments do not show any marked tendency to certain affections, one could feel assured from the following letter:

"That is a very interesting subject, and I wish I had some definite data to go upon to answer your questions. Unfortunately, I have not, nor do I know exactly where you will get it. Do let me hear the results of your investigations.

"Very truly yours,

"(Signed) W. Osler.

"Baltimore, May 4, 1904."

Similarly negative replies were received from other clinicians of wide experience. Some of the answers were more specific. I give herewith the questions sent, and the general tenor of the replies.

1. Are the performers on wind musical instruments more or less subject to (a) catarrhal conditions of the respiratory tract?

All my correspondents, except one, agree that such performers are not more susceptible to such affections. The exception is the Surgeon-General of the German Army, who says that the musicians of the Prussian Army "show a special inclination to emphysema, and in connection therewith to catarrhal diseases of the lungs." The Surgeon-General of the Austrian Army says that musicians are more rarely in military hospitals on account of bronchitis and pneumonia, perhaps because of less exposure than other soldiers. Fully half the musicians heard from (both of orchestras and bands) believe from their observations that catarrhal troubles are less frequent than in other occupations.

(b) Are they more or less subject to pneumonia?

The replies were that they are neither more nor less subject to this disease.

(c) Are they more or less subject to emphysema?

This disease seems almost unknown to musicians, either under the technical name or explained as an "overdistention of the lungs." One prominent bandmaster of many years' experience writes that he has had his physician explain to him the affection, and that he has never known anything of the sort. Mr. Louis C. Elson of Boston says "they are sometimes subject to emphysema." Dr. Tyson writes that they are more subject to the disease. As quoted above, the Surgeon-General of the German Army says they "show a special inclination to emphysema," but gives no statistics. (The mention of catarrhal troubles in connection would, with the theories before mentioned, make one wonder which came first in the case of these men). The Surgeon-General of the Armies of Austria thinks that players on the larger instruments are inclined to emphysema. I have already mentioned the lack of evidence on this subject from the pathologists to whom I have written.

2. Are they more or less subject to tuberculosis?

Most of the physicians say their knowledge of such cases is very limited, and it certainly has not impressed them that such men are more subject to this disease. Dr. Knopf gives me the following statement: "Musicians performing on such instruments offer a relatively great mortality statistic from tuberculosis and morbidity statistic of catarrhal conditions for the following reasons: Many men with inferior physique choose music as a profession, thinking it to be a light and easy way of making a living. Not infrequently these people have a distinct hereditary tuberculous predisposition; furthermore, the majority of musicians play indoors, in dusty, badly ventilated and overheated ball rooms, concert halls, dining rooms or theaters. Strauss (La Tuberculose et son Bacille) found tubercle bacilli in the nasal mucous membrane of nearly all the members of the orchestra of the Paris Opera House. On the other hand, in Europe, and particularly in Germany and France, the military bands are composed of men who must be physically up to the standard of the average soldier, and a part of their training is military. These military bands play mostly outdoors, and show to the best of my knowledge no greater or less morbidity or mortality from the respiratory organs than the rest of the army." He says that his personal experience with such persons has been limited. Dr. Trudeau writes me: "It is impossible for me to give you much information in regad to performers on wind instruments, as my experience with such patients has been very limited. All I can say is that I can remember but very few cases of tuberculosis that have come under my notice occurring in such people. My experience has been so limited, and I have seen so few of them, that I do not venture to answer your question."

The Surgeon-General of the Austrian Army writes me that the musicians of his army are not more inclined to tuberculosis than other men in the service. The Surgeon-General of the Italian Army writes that he "has never observed or heard that other military physicians have observed a special, evident influence (favorable or unfavorable) upon the development of tuberculosis due to playing on wind instruments." The Medical Director of the Armies of England writes that he has "no exact information, but there would appear to be danger of mouth infection through the same instruments being used by different performers."

I have the following from Mr. Innes, Director of Innes' Band: "I have employed a great many musicians from time to time, and the only member of my band who suffered from tuberculosis was a man who played the string bass (not a wind instrument)." Mr. Brooke of the Chicago Marine Band writes: "I have had thirty-eight years' active experience with wind instrument players.

and have never known one to die of tuberculosis, except where the case was directly traceable to the excessive use of cigarettes." Mr. Hindley of the Knickerbocker Theater (New York), who has had forty years' experience, says: "The few who died from tuberculosis in my experience have been mostly those who have lived an irregular and very often a dissipated life." Mr. Carl Clair, Bandmaster of Barnum & Bailey's Circus, writes: "I have been following circus work for the past eighteen years, thirteen years Bandmaster of Barnum & Bailey's Circus with a band of thirty to forty musicians, and during this time have had hundreds of different men under my direction, and never knew of one being troubled with any disease of the lungs." C. G. Conn, the largest manufacturer of wind instruments in this country, thinks players on these instruments are less subject to tuberculosis. Mr. Arthur Brooke, flutist of the Boston Symphony Orchestra, writes: "The only cases of consumption I have known have been three oboe, one trombone, one French horn, and one clarinet player; but every one of these I can trace to dissipation, either in younger days, or continued use of liquor, except the clarinet player, who came, I am told, from a consumptive family." Mr. Louis C. Elson of the New England Conservatory, who has had a wide experience with musicians of this country and Europe, says: "They are less subject to tuberculosis—much less." Monsieur A. Lavignac of the Paris Conservatory writes: "They claim that they are less subject to tuberculosis, but in the Conservatory of Paris I have had occasion to testify to several cases of pulmonary tuberculosis during several years with the wind instruments." (A gentleman who is acquainted with the lives of these young Parisian musicians volunteers the suggestion that their extreme dissipation is sufficient to account for all their diseases). Mr. Krehbiel, the eminent musical critic of New York, writes: "In my acquaintance, say of thirty years, with orchestral players, I can recall only one case of death from pulmonary troubles. That was the case of a cornet player, and I do not know that his profession had anything to do with his death."

I have given only the more interesting replies. Summing up the whole of my correspondence with musicians, I find that about one-half think tuberculosis not more frequent, and the other fifty per cent. believe it to be less frequent among such performers.

3. What is the percentage of deaths from tuberculosis among such performers?

The only reply giving anything valuable in the way of statistics is from the Surgeon-General of the German Army. A special study of tuberculosis in this army, made in 1898, the investigation covering a period of eight years of service. Each department of the army was grouped separately, and the following are some of the percentages from this disease per 1,000: Infantry, 1.8; field artillery, 1.8; cavalry, 1.9; light artillery, 1.9; musicians, 4.1; mechanics, 4.6; tailors, 5.0; laborers, 6.0; bakers, 7.3.

The number of musicians was 5,897, of which about 92 per cent. were players of wind instruments. Aside from the fact that the 8 per cent. who played the percussion instruments might influence the total somewhat, the figures may be considered as of the highest value.

In the armies of the United States, of England, Austria, and of Italy, the musicians are not grouped in separate health reports. Mr. Louis Elson says that "in Italy careful statistics covering ten years failed to show a single death from tuberculosis among trombone players."
